Nuclear power can operate in cogeneration mode or a heat-only mode; all current nuclear power plant concepts are potentially applicable to cogeneration (International Atomic Energy Agency, 2002). Concerns about radioactivity being distributed through a district heating network are eliminated with thermal transfer that occurs in a secondary or tertiary exchange loop that fully decouples the reactor from the transmission and distribution systems (Nuclear Energy Agency, IAEA, 2013). Interest and application of nuclear generation for district heating purposes dates back several decades. Compared with other generation sources, nuclear power provides more energy security than some other fuel generation sources due to fuel density and long cycles of operation between refueling (Joint Institute for Strategic Energy Analysis (JISEA), 2020). This is especially relevant in climates where winter weather can cause disruption to rail or other transportation of fuels such as coal or oil (International Atomic Energy Agency, 2002). Nuclear generation also operates as a clean fuel source, reducing air pollution and greenhouse gas emissions (Joint Institute for Strategic Energy Analysis (JISEA), 2020; Margen, 1978). This was found to be true in Switzerland, which has operated several nuclear power plant-district heating systems, where further benefits include better economic returns when carbon emissions credits are considered and increased political acceptance of nuclear power (Nuclear Energy Agency, IAEA, 2013).

The use of waste heat from nuclear generation can increase the overall thermal efficiency of the plant and provide another revenue stream aside from electricity (Joint Institute for Strategic Energy Analysis (JISEA), 2020). A study of district heating in Helsinki showed that switching the generation source from coal and natural gas to a nearby nuclear power plant could reduce carbon dioxide emissions by up to 4 million tonnes annually. However, the study also showed that a major challenge would be the long distance piping network that would be required to connect the nuclear plant to the Helsinki heating system, presenting an economic constraint (Nuclear Energy Agency, IAEA, 2013).

There are some key challenges related to utilization of a nuclear power plant as a source for district heating. Existing reactors typically produce 500–1500 MW of electricity, plus approximately twice as much waste heat. This thermal output is likely far larger than demands for district heating within proximity of conventional nuclear power plants (International Atomic Energy Agency, 2002). The distance between nuclear power plants and the dense urban centers where residential and commercial district heating is most efficient can require considerable transmission network development (Nuclear Energy Agency, IAEA, 2013). This is noted as the major barrier for implementation in many countries even where district heating is already used for a high percentage of home heating needs (Werner, 2017). This is exemplified in a techno-economic analysis of switching two district heating networks in France to a nuclear generation source. The study found no technical hurdles for implementation. However, it noted that the major challenge to implementing a nuclear-fueled district heating system would require network modifications and a lengthy transmission network to connect generation and distribution components of the system. In some regions, the resulting costs (potentially exceeding 10 million Euros per kilometer) may limit the application of conventional nuclear facilities situated far away from the denser population centers (Jasserand and Devezeaux De Lavergne, 2016). Another challenge for nuclear generation in district heating is the refueling cycle of large plants. Outages may be problematic for generation stations with a single, large reactor and thus require backup generation units that add to the overall costs of operation (Jasserand and Devezeaux De Lavergne, 2016). However, the planned timing for outages could consider seasonal demand and potentially avoid this challenge. A final challenge associated with nuclear reactor operation, especially as heat-only sources, is the licensing and regulatory framework governing nuclear plant operations. In some countries, the regulatory framework for existing nuclear power does not account for heat-only and/or cogeneration options, requiring legislative changes and potential time and monetary costs to account for new operational flexibility (Värrö and Syri, 2019).

A 1987 technical document from the International Atomic Energy Agency (1987) collates experiences from existing district heating applications (nuclear and non-nuclear generation sources) from member states to identify key benefits and considerations for expanding the systems within different regions. Studies and/or operational experience from 10 nations identify the technical data for types of reactors, power ratings, coolant/moderator used, type of design and circuit configurations, temperatures and pressure and other key features in operation or under investigation.

Current state of district heating deployment globally

District heating systems account for approximately 6% of global heat consumption, with China and Russia constituting the majority of use (International Energy Agency, 2019). Renewables account for approximately 3–4% of district heating globally, with Germany, China, Austria and Sweden slightly above this value and Denmark, Russia and Finland closer to 20% of generation from renewable sources (International Energy Agency, 2019). In China and Russia, estimates are that over 200 million persons are

currently supplied by district heating systems (Mazhar et al., 2018). One estimate for the market size of district heating in 2019 was USD\$137 billion in Europe and USD\$173 billion globally (Fortune Business Insights, 2020). This is expected to increase in the latter half of the 2020 decade to over USD\$200 billion, with growth largely driven by desires to reduce emissions (Fortune Business Insights, 2020; Global Market Insights, 2020). The International Energy Agency has a collaborative effort on CHP and district heating and cooling systems, and provides periodic reports on progress in different countries relating to state of research, deployment and systems integration (International Energy Agency, 2021).

District heating is widely deployed in several countries. While not an exhaustive list, Denmark, Finland, Sweden, Germany, Poland, Russia and China have long historical experience with district heating and relatively high penetration of networks that serve heating needs. In Denmark, electricity production is split between small and large-scale CHP providers, with a net production of nearly 20,000 TWh in 2006. Of this, 285 decentralized plants are CHP producers, 16 are centralized (larger) CHP plants and an additional 130 centralized district-heat only plants (International Energy Agency, 2008a). Together, these meet nearly 50% of the heating demand for the country and are estimated (as of 2004) to have saved 8–11 million tonnes of carbon dioxide emissions annually (International Energy Agency, 2008a). The network length is estimated at 29,000 km (Mazhar et al., 2018). Copenhagen has an integrated network that has been serving 270,000 households for many decades, with a transmission network length of 54 km and integration with power systems, natural gas and waste management systems (Mazhar et al., 2018). All cities in Finland have operational district heating systems, serving just under 50% of collective heating requirements, with CHP generation accounting for around 80% (Värrä and Syri, 2019). The Finnish systems produce approximately 13.5 TWh annually from CHP plants, of which approximately 20% is from renewable generation sources (Mazhar et al., 2018). In 2017, Finland's nuclear power energy production was approximately 30% of the total energy produced, while renewables including wind, wood-based fuel and hydropower was just over 50% (International Atomic Energy Agency, 2019a). In Helsinki, more than 90% of the buildings are served through district heating networks, although most CHP plants are powered by higher emitting fossil fuels and a key consideration for reaching climate commitments is the reduction in generation source emissions (Värrä and Syri, 2019). In 2015, Sweden estimated that 55% of heating needs were covered by district heating. Commitments to move towards cleaner generation sources resulted in a reduction in fuel oil for generation to nearly zero use, compared with a 1970 high of almost 80% (Werner, 2017). An early example of district heating fueled by nuclear power was the Ågesta reactor operating south of Stockholm, which provided 10 MW electricity and 70–80 MW thermal heat for district heating use. However, its small size and early deployment led to unfavorable economic returns and it was shut down several decades ago (Märgen, 1978). Germany is the largest energy market in Western Europe and 29% of the final energy is consumed by households, of which almost 90% is used for heating and hot water generation (International Energy Agency, 2008b). District heating is estimated to serve approximately 14% of heating needs in Germany, with production exceeding 70 TWh in 2015 and an estimated network length of approximately 20,000 km (Mazhar et al., 2018). The district heating network in Poland serves approximately 40% of the population through nearly 500 operators, with the majority of generation through CHP. In Warsaw, over 80% of heating demand is supplied through district heating networks, with a production of 11 TWh annually and 1600 km of installed piping (Mazhar et al., 2018). Russia has the largest network globally and one of the longest operational histories for district heating. The estimated network length is 200,000 km carrying over 1700 TWh of heat annually serving 70–80% of the country's heating demand (Mazhar et al., 2018). The Russian network is largely supplied through CHP, primarily natural gas and coal, but has an operational history with nuclear power plant generation dating back many decades (International Atomic Energy Agency, 1987). Extensive operational history, experience and research in district heating, including nuclear power generation, can be found in several publications from the International Atomic Energy Agency (e.g., International Atomic Energy Agency, 1977, 1987, 2002).

Nuclear power and district heating

The current deployment of nuclear reactors for district heating is a small overall percentage of CHP generation, totaling just over 2.1 GWh of equivalent heat in 2018 (Joint Institute for Strategic Energy Analysis (JISEA), 2020). This was supplied by 58 reactors cogenerating or dedicated to district heating purposes (Joint Institute for Strategic Energy Analysis (JISEA), 2020). Considering that nuclear power currently supplies over 1/3 of the world's low carbon energy globally (Joint Institute for Strategic Energy Analysis (JISEA), 2020), interest in "flexible" nuclear power plant operations is increasing. This is evident in the launch of the *Flexible Nuclear Campaign* at the Clean Energy Ministerial's 10th annual meeting in 2019, where integration of cogeneration systems including district heating were highlighted (Joint Institute for Strategic Energy Analysis (JISEA), 2020). In China, the first commercial nuclear heating project came online in November 2020. The Haiyang power plant operates two AP1000 units where non-radioactive steam is extracted from the secondary circuit of the reactors and fed through an on-site heat exchange station, which feeds an off-site circuit. The latter is connected to a heat exchanger which sends heat to a local thermal company (World Nuclear News, 2019a). The nuclear power plant provides approximately 20 TWh of electricity annually and currently provides district heating serving over 700,000 sq. meters of housing, with plans to expand by the end of 2021 to serve up to 30 million sq. meters (World Nuclear News, 2019a, 2020). The operation of this facility is estimated to offset the use of 23,200 t of coal annually, reducing air pollution (estimated soot reduction is 222 t per year) and environmental greenhouse gas emissions (estimated reduction of carbon dioxide is 60,000 t per year) from the use of heating generated from nuclear power (World Nuclear News, 2020).

Considerations for current and future development

Climate and environmental aspects

Increasing concerns around air pollution and greenhouse gas emissions and commitments to clean and sustainable energy systems continue to grow. A recognition that a climate change will impact the energy demand for heating and cooling introduces additional uncertainty into future planning, although climate models can provide some insight into the magnitude and location of selected changes, [Fig. 3](#). Most countries have committed to rapidly decarbonizing their economies, including the energy sector ([United Nations Framework Convention on Climate Change, 2015](#)). A 2015 estimate showed that buildings in the European Union produced 634 million tonnes of non-emissions trading system (non-ETS) greenhouse gas emissions ([European Environment Agency, 2020](#)). Cogeneration systems have been specifically identified as one way to achieve with 10s of TWhs in thermal generation possible from CHP, including nuclear power, if the existing challenges including longer transmission distances could be addressed ([Jasserand and Devezeaux De Lavergne, 2016](#)).

Some evaluations of decarbonizing the district heating sector do not include consideration of nuclear power in future investments (e.g., [Lund et al. 2014](#)). However, increasing global recognition of the role nuclear power must play in “de-risking the pathways to significantly lower emissions” to create more clean, affordable and resilient technology portfolios is ongoing ([Jasserand and Devezeaux De Lavergne, 2016](#); [Joint Institute for Strategic Energy Analysis \(JISEA\), 2020](#); [Parsons, 2021](#)). One promising possibility for district heating with nuclear power generation systems is found in small and micro modular reactors systems (SMRs) ([Ingersoll, 2021](#); [Wallenius, 2021](#)). In Canada, the testing of district heating systems as a cogeneration option for SMRs is ongoing ([Joint Institute for Strategic Energy Analysis \(JISEA\), 2020](#)). Designs capable of district heating are currently available from multiple countries. The South Korea SMART reactor (System-integrated Modular Advanced Reactor) is a 330 MW (thermal) SMR that could be used for district heating. The reactor was certified by Korean Nuclear Safety and Security Commission in July 2012 ([International Atomic Energy Agency, 2019b](#)). In September of 2015, a pre-project engineering agreement was signed with the Kingdom of Saudi Arabia for the deployment of SMART in Saudi Arabia ([International Atomic Energy Agency, 2018](#)). The Akademik Lomonosov reactor, has been installed in Pevek, Russia and became operational at the end of 2019. It is comprised of two 35 MW (electric) reactors of the KLT-40S floating model ([International Atomic Energy Agency, 2021](#)), housed on a non-self-powered barge measuring 144 m long by 30 m wide ([World Nuclear News, 2019b](#)). In addition to electricity, the each of the Akademik Lomonosov reactors provide 150 MW (thermal) of heat, and include additional cogeneration capabilities of supplying fresh water in capacities up to 240,000 L each day ([Golay and Kadak, 2021](#)). The Akademik Lomonosov replaces two existing power plants, including a coal-fired plant, saving an estimated 50,000 tons of carbon dioxide emissions per year ([Boyd, 2019](#)). In the US, the NuScale reactor is in the final stages of licensing and is capable of providing electricity and thermal energy for district heating systems ([International Atomic Energy Agency, 2018](#)). The NuScale modules, 160 MW (thermal) each, are designed to operate in packs of up to 12 modules, allowing for flexible cogeneration options where some modules provide heating and others provide electricity ([NuScale Power, 2021](#)). Additionally, the US Nuclear Regulatory Commission granted NuScale’s system a site boundary emergency planning zone. This feature, which is expected to be a common feature of SMR, would greatly reduce the length of transmission networks required to convey heat between generation source and distribution end use, thus reducing system costs ([NuScale Power, 2020](#)).

Other aspects

The continued development and greening of the energy sector includes upgrading existing district heating systems and developing new, integrated systems. This is a multi-faceted, challenging and complex issue. As new systems are developed, an emphasis on systems that integrate heating and cooling are being developed as part of a more sustainable “fourth generation” of district heating often called “cold district heating” ([Lund et al., 2014](#)). In an integrated system, cold and hot water are moved between buildings depending on individual needs with heat pumps moving thermal energy into or out of a building. Such systems could allow for better year-round demand from CHP plants and build on expertise developed in district heating ([International Atomic Energy Agency, 2002](#); [Werner, 2017](#)). The consideration of cooling may be especially important as warmer regions of the world, where energy poverty and electrification are major focus areas of development efforts, continue to industrialize and where demand may increase significantly as electrification is increased. [Fig. 3A](#) and [B](#) show current global estimates for heating degree days (HDD) and cooling degree days (CDD), a measure of building energy use that calculates the difference between ambient and indoor air temperatures (e.g., [Moustris et al., 2015](#)). [Fig. 3C](#) and [D](#) show the estimated increase in HDD and CDD globally, using the 2050 decade and a median climate model ([NASA Center for Climate Simulation, 2019](#)) (Model represents the median model from the CMIP5 RCP4.5 ensemble, based on average heating and cooling degree days in Paris, France in the year 2050. Data from authors’ calculations.). These figures show that both cooling and heating have significant demand globally, although they vary spatially. Looking out to the 2050 decade, very little (if any) increase is expected in heating degree days globally for the climate scenario shown. By contrast, cooling degree days are expected to increase 25–50% throughout most of the tropics, a region with already underserved populations for energy demand in many locations.

A challenge to the deployment and upgrading of existing systems, especially for nuclear power, is the regulatory frameworks within different countries that govern their licensing, inspections and operations. For countries with existing nuclear infrastructure, the regulatory framework might not currently cover operations for heat production, an issue identified in France ([Jasserand and Devezeaux De Lavergne, 2016](#)). For countries without any current nuclear regulatory infrastructure, the need to develop this alongside the technology presents additional considerations.

Fig. 3 Estimated annual heating and cooling degree days in the current climate (A and B) and estimated future changes (C and D). Future changes are in percentage relative to the current climate. Future estimates are based on a median climate scenario from the CMIP5 RCP4.5 data and calculated by the authors.

Finally, broader reasons outside pure economic and environmental impacts may incentivize the consideration of new or expanded district heating networks, especially those powered by clean fuels including nuclear power. Energy poverty is very high in some developing regions of the world and electrification investments are ongoing, and many of these regions are expected to continue to increase in demand, especially for cooling (see Fig. 3D) (Bhatia and Angelou, 2015). However, energy poverty also exists within more developed economies. A particularly high burden for many households is the resources required for fuel (Bednar and Reames, 2020). For example, in the United Kingdom, one estimate puts fuel poverty at 11% (Mazhar et al., 2018). In the US, 2015 estimates showed that 25 million households (about 20% of total in US) had to forgo food and medicine to pay energy bills (Bednar and Reames, 2020). These issues may be exacerbated by changing climates, with energy being an integral part of the complex nexus of poverty and vulnerable populations (Jessel et al., 2019).

Summary

District heating is widely used in many regions of the world and can be produced by heat-only generators or as a by-product of existing power plants through cogeneration operations. Cogeneration from nuclear power presents both challenges and opportunities, including the benefits from clean, reliable energy production as well as the costs associated with the transmission of heat from large, conventional facilities located tens or hundreds of kilometers away from dense urban centers where district heating is most widely used. However, there are instances where nuclear-powered district heating has been and is currently deployed, and as concerns around greenhouse gas emissions continue to take a priority, nuclear power generation is being considered in many new locations. Examples of this, specific to district heating, include the Haiyang Chinese power plant (very large) and the Akademik Lomonosov SMR in Russia (total design of 70 MW (electric)). In emerging fourth generation district heating designs, an integrated systems deployment including consideration of cooling needs, electricity and other operations can result in more optimized energy delivery and reduction in greenhouse gas emissions (Lund et al., 2014). The potential of SMR and MMR technology is particularly relevant in the planning of integrated systems. This is due to the smaller, more flexible units that include additional safety considerations, standardized designs, and siting parameters that allow for use nearer to populations and flexibility for deployment at varying sizes. These parameters make SMR technology more applicable in many areas that currently experience energy poverty and may play a role in both replacement and new power plant builds.

Introduction

Sustained growth of renewable energy generation in the U.S. has imposed economic challenges on many large, traditionally baseload-generation plants. Many plants within the domestic nuclear fleet have been or will be economically challenged when these plants are required to operate at less than full capacity either seasonally or daily when sufficient renewable resources are available to support grid demand. As renewable output decreases, however, nuclear plants are critical to ensuring that grid demand is met. Several utilities and operators of these nuclear plants in the U.S. are investing in integrated energy systems (IES) that can supply dispatchable loads to integrated energy users to maintain full output during low demand times; supply to non-grid energy users can then be reduced when power is needed on the grid.

At the same time, availability of potable water is already a limiting factor in local population growth and wealth for several areas of the U.S. and worldwide. Several major reports from large international organizations (IAEA, 2007) identify the availability of fresh potable water as a major challenge for future growth.

The IES paradigm shift recasts those two challenges as an opportunity. An integrated regional desalination process provides for additional or dispatchable loads (up to 100 Megawatt (MW) electric) that may help avoid nuclear energy generation curtailment during the day while producing potable water. Later, Nuclear Power Plants (NPPs) can reduce output of the coupled desalination plant to facilitate greater power output to the grid. This integrated process provides valuable grid capacity along with large-scale production of potable water.

As a specific example for U.S. markets, the municipalities west of Phoenix, Arizona, are presently experiencing challenges to sustaining growth because of limited water resources. As groundwater and surface water resources are stressed, these municipalities are now focusing on other, lower quality brackish groundwater resources that are available and sustainable in large supply. Use of these resources is dependent on cost-effective desalination and management of the process concentrate or reject stream.

There are limited options for the management of the treatment process concentrate from a large-scale municipal water treatment facility. Deep well injection in the shallow Phoenix sub-basin is improbable, plus the injection process currently lacks the required authority in Arizona. Surface evaporation ponds are very expensive and require significant surface area for the large-scale municipal projects. These options are cost-prohibitive and provide an incentive to consider other, more cost-effective and innovative options. The Palo Verde Generating Station (PVGS) is located nearby and could benefit from the dispatchable load of a regional reverse osmosis (RO) water treatment facility, and can process the regional system concentrate. Selection of the most cost-effective technology is needed to optimize design and maximize economic value.

The Arizona Public Service (APS) utility, which serves as the operating owner of PVGS, which comprises three nuclear units, could benefit from the introduction of a large load-modulating resource such as a desalination plant. In particular, this would allow increased penetration of variable renewable energy, especially solar photovoltaic generators, while preserving the value of PVSG as a large baseload, carbon-free asset on the regional electric grid.

Desalination technologies overview

There are several processes that have been demonstrated for producing clean water from saline-rich water (either brackish or salt-water). Still, global experience with desalination plants coupled to nuclear reactors is dominated by three primary processes: two distillation-based technologies (multiple-effect distillation (MED) and multi-stage flash (MSF)) and one membrane-based technology, reverse osmosis (RO) (International Atomic Energy Agency, 2000) as shown in Table 1 (Al-Othman et al., 2019). In fact, according to a recent IAEA publication on nuclear cogeneration (International Atomic Energy Agency, 2017), the global use of nuclear energy for desalination applications has accumulated over 250 years of reactor operation, when tallied across all nuclear-desalination units. Other purification technologies like Vacuum Membrane Distillation, Vacuum Compression Desalination (VC), Forward Osmosis, and Electrocoagulation have potential long-term opportunities, but are not presently at scale relative to the process rates considered.

MED consists of multiple stages, each at descending pressure. Saline water in each stage is heated to vaporization. Vapor from each stage is condensed in the next successive stage, thereby giving up its heat to drive more evaporation. Seawater is then sprayed over these hot tubes to evaporate the water. The vapor created from condensing the previous effects vapor is then streamed to the next effect. To avoid mixing the boiler chemicals with the pure distillate, the distillate from the first effect does not join the main distillate stream. The brine is collected at the base of each effect, which is either circulated to the next effect or transported out of the system, as illustrated in Fig. 1 (Miller, 2003). The use of MED fell from favor in the 1950s due to scaling on the tubes which caused thermal degradation. However, in recent years MED has been making a resurgence as corrosion and scaling science have matured (Saadat et al., 2018).

Desalination using MSF is based on heating seawater in a brine heater to around 100 °C. The hot brine then enters a flash chamber, which is held at vacuum. Since the water entering the chamber is above the boiling temperature at vacuum, part of the water flashes to steam. This steam rises to condensing coils where it condenses into fresh water. A diagram of this process is shown in Fig. 2.

MSF is a proven technology for water desalination. It is a simple and extremely reliable process that requires no moving parts other than pumps. However, MSF is more energy intensive than current RO plants. MSF also requires a direct steam connection to

Table 1 Nuclear desalination plants across the world.

Country	NPP type	Desalination technology	Water capacity (m ³ /day)	Status
India	PHWR (Kalpakkam 1,2)	Hybrid MSF/RO	6300	Operational
Japan	PWR (Ohi 1,2)	MED	(2 × 1300)	Operational
		MSF	(1 × 1300)	
		RO	(2 × 1300)	Operational
	PWR (Ohi 3,4)	MSF	(2 × 1000)	Operational
	PWR (Ikata 1,2)	RO	(2 × 1000)	Operational
	PWR (Ikata 3,4)	MED	(1 × 1000)	Operational
	PWR (Ginkai 3,4)	RO	(1 × 1000)	
	PWR (Takahama 3,4)	MED/VC	(2 × 1000)	Operational
	BWR (Kashiwazaki)	MSF	(1 × 1000)	Not used
Pakistan	PHWR (KANUPP)	MED	1600	Operational

Fig. 2 Example of a multistage flash desalination plant.

the power plant, and typically cannot operate at less than full capacity due to its system design and to limit potential system instabilities (Darwish and Al-Najem, 2000). These challenges limit MSF's applicability to integrated energy systems where a non-uniform load would be sent to the desalination process as demand fluctuations occur on the grid.

The main competitor to multistage flash desalination is RO. The RO process works by passing water at high pressures through fine membranes that only allow water molecules to pass. A typical RO plant works in two stages. First is a pretreatment stage where chlorine and other chemical additives are used to remove biological organisms and control both the pH and hardness of the water, i.e., the amount of dissolved solids in the water such as magnesium, calcium and others. The water is then sent to the membrane filtration system where high pressure forces the water molecules through the membranes into an inner collection tube. A representative diagram of an RO system is shown in Fig. 3.

Reverse Osmosis has the benefit of consuming less energy than MSF. Also, RO does not need a direct steam connection to the power plant as it only requires electric energy to run pumps and has simple start/stop operating capability (Darwish and Al-Najem,

Fig. 3 Example of a Reverse Osmosis (RO) plant.

2000). Since RO is operated in modules, operation can be staged to take advantage of available excess energy instead of the continuous full operation of MSF. RO processes also consume less energy than MSF.

The choice of desalination method(s) is determined primarily by the characteristics of the source water and the water quality required by the end user. For example, RO technology typically has a lower capital cost but is less effective with feedwater that contains high levels of organic materials that can foul the membranes or that have high salinity levels and can only produce potable water without further treatment. The two thermal distillation processes are much more tolerant of “dirty” or “salty” feedwater and produce high-purity water.

Connection and control with NPPs

A key distinction in the two desalination methods, namely distillation and membrane-based processes, is how they couple with a power source. The RO plant has the most straightforward coupling since it operates using only electricity, which is needed to run the high-pressure pumps. Therefore, it is not essential to co-locate the desalination plant with the power plant so long as a grid connection is available. However, there may be an advantage for co-location of the power and RO desalination plant in terms of shared infrastructure and protection against grid disruption. Also, low grade steam or warm wastewater from the power plant can be used to preheat the saline feedwater of the RO plant to improve its clean water production efficiency, although the quality of the distillate may be adversely impacted.

Both MED and MSF plants require a thermal heat source, such as a steam line from the secondary side of the NPP. For NPPs this steam would typically be extracted either by the high-pressure or low-pressure tap on the turbine. Since energy quality requirements for MSF and MED are low, the heat could be extracted from a low-pressure turbine stage. For space-constrained power plants or steam cycles that preclude such integration, it is possible to take the higher quality steam from the steam generator through an existing bypass valve and use it for distillation.

Economics

Several factors are needed to understand the potential cost of potable water produced through a coupled nuclear-desalination process (Ingersoll et al., 2014): (1) energy requirements of the desalination processes both thermally and electrically, (2) the

Table 2 Specific energy consumption of desalination plants.

Process	Specific heat consumption (kWt-h/m ³)	Specific electricity consumption (kWe-h/m ³)
MSF	100	3
MED	50	2–3
RO	0	4.5

International Atomic Energy Agency (2007) *Economics of Nuclear Desalination: New Developments and Site Specific Studies. Final Results of a Coordinated Research Project 2002–2006.*

cost of that energy, and (3) the cost of the integration between the nuclear plant and the desalination process. Energy consumption for each of the main three desalination processes are summarized in [Table 2](#).

The cost of the energy required to produce the water is market specific, as it can be considered the maximum of the opportunity cost of the NPP not producing electricity to the grid or the operational and maintenance cost of the nuclear plant, as expressed below.

$$Energy_{Cost} = \max(\text{market}_{price}, O\&M_{NPP})$$

This expression holds because the plant operator always aims to maximize profit. If more profit can be created by selling to the grid, then the desalination plant will have to match this price to purchase the power. Alternatively, if the market price is below cost of operations and maintenance (O&M) of the plant, then the plant operator would decide to shut down the plant rather than sell to the market. Thus, the desalination plant would need to purchase power at the O&M cost. While there are scenarios in which this is not always the case (depending on market structure and ownership of the plants), it is sufficient to say that even with this simplified formulation it is difficult to specify a precise energy cost.

The cost structure is also impacted by the physical integration approach. For a generic off-the-shelf RO plant, integration is electrical only, thus requiring minimal expenditures even if the RO plant is integrated with the NPP behind the NPP connection to the grid (the RO plant could also be grid-connected). If efficiency needs to be boosted, feedwater pretreatment can be added if NPP waste heat is already heading to the condenser. Integration of MSF and MED is far more involved. These processes require a tap off the high-pressure, medium-pressure, or low-pressure turbine along with associated control schemes.

According to a 2007 IAEA report, economics of nuclear-desalination is site specific and is dependent on several factors and the economic assumptions used. However, the case studies have shown that, in general, nuclear desalination costs can vary from 0.5 to 0.94 \$/m³ for RO, from 0.6 to 0.96 \$/m³ for MED and from 1.18 to 1.48 \$/m³ for MSF plants (IAEA, 2007). Further studies have shown that RO technology, given the superior efficiency, is generally more cost effective than MSF or MED.

Providing regional potable water in Arizona

An example is presented here to illustrate how case dependent benefits and peculiarities—such as cooling water production—can play into the economics of nuclear driven desalination. A techno-economic study conducted in 2018–19 (Epiney et al., 2018, 2019) analyzed the economic viability of an Integrated Energy System (IES) that couples an RO water desalination facility with an NPP in the Southwest region of the U.S. The case study was conducted by Idaho National Laboratory (INL) in collaboration with APS, which is the operating owner of the PVGS NPP.

Palo Verde is the largest nuclear single site facility in the U.S., generating on average 32,000,000 Megawatt hours (MWh) electric annually and providing significant regional grid stability. However, sustained growth of renewable generation in this region has resulted in seasonal over-generation and consequential frequent low-power pricing. Palo Verde is also the only nuclear facility in the world not located on or near a natural body of water. Cooling water for the reactor steam cycle is derived from municipal wastewater of the Phoenix area (effluent). The wastewater is pre-treated in treatment plants near the municipalities and is conveyed to an additional onsite tertiary treatment facility at Palo Verde that further treats the water to plant chemistry standards. The cost of the municipal effluent escalates annually and represents an increasing fractional cost of generation.

Efforts to reduce cooling costs have identified alternative water sources to replace the increasingly expensive effluent. Brackish water from a regional aquifer is available in large supply and is sustainable. The quantity of brackish groundwater that could be used for plant cooling is limited because of high salinity and the potential of scaling in system components. The Palo Verde tertiary treatment facility can treat the increased hardness that would result from a blend of the groundwater with the effluent. However, several constituents such as chlorides are not affected by the treatment process and, in sufficient quantity, would result in levels that exceed the operational limits in the PVGS circulating water system and evaporative cooling towers. Consequently, supplemental treatment would be required to specifically address these constituents such that a greater amount of brackish groundwater could be used to reduce the demand on effluent.

Evaluations of supplemental treatment options suggest that a higher concentrated blend of effluent and brackish water could be processed while maintaining the Palo Verde water balance when only a fraction of the total tertiary treated water mixture undergoes the supplemental treatment. Moreover, the cooling water loop chemistry at PVGS allows for the supplemental treatment system to

Fig. 4 Phoenix west valley region including PVGS, the municipalities of Buckeye, Goodyear, Avondale, Tolleson and Phoenix downtown. Google Maps.

be sized such that it could also support concentrate management for a regional desalination plant. The desalination plant could process brackish water in the regions and provide significant value to the Phoenix west valley municipalities that are currently growth-challenged due to the limited availability of potable water (see Fig. 4).

The INL study investigated the economics of blending a fraction of the regional brackish water to offset a corresponding amount of effluent. Due to constraints that limit concentration of select water constituents in the Palo Verde cooling water, the economics continue to favor the use of effluent. Consequently, the INL assessment considered the integration of the regional RO facility and a supplemental treatment process at Palo Verde to manage the regional concentrate to provide an alternative water supply to the surrounding municipalities. The economic assessment considered the market value of the potable water and the benefit of concentrate management in this area. Options are limited and not economically viable considering that deep well injection is not authorized and surface evaporation ponds require large tracts of land and have high capital cost.

The investigated case considers building a regional RO desalination plant (designated RO2) near the regional waterlogged area where the brackish water reserves exist in the shallow aquifer. Concentrate from the regional RO (designated RO2) desalination plant could be transported in the pipeline that conveys the municipal effluent from the municipal wastewater treatment plant to Palo Verde. The supplemental treatment process onsite (designated RO1) would ensure that the Palo Verde water balance is maintained. This case is shown in Fig. 5.

The case study has three main degrees of freedom:

- The amount of brackish water sent into the regional RO (i.e., RO2 size).
- The percentage of Water Reclamation Facility (WRF) outlet water treated by RO1 (slip stream designated as α) (i.e., RO1 size).
- The amount of brackish water directly injected into the pipeline between Waste Water Treatment Plant (WWTP) and WRF.

Ranges for the degrees of freedom have been investigated to show impact on the case study economics as well as to find optimal (most profitable) combinations of RO sizes. Fig. 6 shows the Levelized Cost of Potable Water (LCOPW) (color map) as a function of RO1 and RO2 size for 0 m³/year (0 AF/year) and 1.9e7 m³/year (15,500 AF/year) of brackish water directly injected in the effluent water supply line.

In general, the study shows that there exist combinations of regional RO and PVGS RO sizes that satisfy total blowdown and water chemistry limits at PVGS (including regional RO concentrate treatment at PVGS either through increased blowdown or onsite RO treatment). However, possible combinations only exist if no additional brackish water is directly mixed into the tertiary system at PVGS. The lowest LCOPW (~ 0.5 \$/m³) can be achieved with a size of the regional RO of $\sim 1.4e7$ m³/year (11,000 AF/year) capacity, which leads to $\sim 8.63e6$ m³/year (7000 AF/year) of potable water while no onsite RO at PVGS is built.

The maximum-size regional RO that respects the physical boundary conditions can be achieved when no additional brackish water is directly mixed in the tertiary system at PVGS, and a PVGS onsite RO is built that treats $\sim 2.3\%$ of the effluent and regional RO concentrate blend. The corresponding regional RO size is $1.5e7$ m³/year (12,500 AF/year), which is only slightly bigger than the regional RO with the lowest LCOPW (within the physical boundaries). However, the LCOPW for that biggest regional RO is slightly less favorable compared to the case where no RO1 is built. A RO of that size consumes 6.75e4 MWh-e/year.

It is worth noting that for a given total blowdown limit (cooling tower and onsite RO1), the maximum salinity in the reservoir can be higher (i.e., a larger RO2 can be built) when the water is run through the cooling tower (with fewer cycles) and blown down to the evaporation ponds, compared to desalination with an onsite RO. This is because the reduction in blowdown from the circulating water system by having an onsite RO (lower salinity water in cooling loop) is lower compared to the concentrate produced from the onsite RO1. In other words, for a given total blowdown limit, the circulating water system blowdown is more efficient in

Fig. 5 Brackish water is pumped from the ground. Some of the brackish water is purified and sold, while the waste and some of the brackish water is blended with the effluent. The brackish water wells are relatively close to the WWTP and blending waste and brackish water with effluent allows to use the already existing pipeline infrastructure between the WWTP and WRF. This mix needs to be treated in an onsite RO added to the WRF. From Epiney A, Richards J, Hansen J, Talbot P, Burli P, Rabiti C and Bragg-Sitton S (2019) “Case Study: Integrated Nuclear-Driven Water Desalination—Providing Regional Potable Water in Arizona”. INL/EXT-19-55736. Idaho National Laboratory.

Fig. 6 LCOPW as a function of RO1 and RO2 capacity. The brackish water directly into the pipeline is 0 m³/year (0 AF/year) in the left figure and 1.9e7 m³/year (15,500 AF/year) in the right figure. The red box represents the region for which the chloride concentration in the reservoir ponds is below 450 ppm. The black box represents the region for which the total blowdown is under 4.38e6 m³/year (3550 AF/year). The yellow box shows the region for which both the salinity and the blowdown limits are respected. From Epiney A, Richards J, Hansen J, Talbot P, Burli P, Rabiti C and Bragg-Sitton S (2019) “Case Study: Integrated Nuclear-Driven Water Desalination—Providing Regional Potable Water in Arizona”. INL/EXT-19-55736. Idaho National Laboratory.

chloride reduction in the loop than the RO1. However, this conclusion only considers the blowdown limit and not the associated economics.

A developed water market model for the area suggests that bigger regional ROs (beyond 11,000 AF/year) will be even more profitable. However, to dispose of the concentrate of larger regional ROs at PVGS, additional evaporation ponds will have to be constructed. This cost was not considered in the study.

Conclusions

The integrated energy system paradigm successfully addresses a challenge that large, traditionally baseload-generation plants are currently facing. The increase of variable renewable energy generation creates high volatility that decreases the amount of the

demand that can be addressed with baseload suppliers. Within the IES concept, baseload generators are not anymore exposed to the volatility of the demand of the grid. The demand is internally stabilized by the presence of a variable load. The integrated baseload suppliers can maintain full output during low electricity demand times. Supply to non-grid energy users is reduced when power is needed on the grid. Using this integrated system approach, traditional base-load plants like NPPs can stay economically viable which is important not only to secure continuous electricity supply, but also enhances grid stability to which large rotating machines contribute considerably. The illustrative study for a regional RO integrated with PVGS shows that case dependent benefits and peculiarities such as electricity market structure and possible cooling water production can play favorably into the economics of nuclear driven desalination. This case shows how IES is not only about the introduction of variable, off the grid baseload, but it is a more holistic approach where all the feedstocks, waste, electricity co- and by-products are considered with respect to the enhancement of the financial and socioeconomic metrics of the project.

Introduction

The transportation sector contributed 28% to the total greenhouse gas (GHG) emissions in the U.S. in 2018. Of all the GHGs emitted by the transportation sector, 41.2% were emitted from passenger cars, 17.4% from light-duty trucks, with the remaining 23.2% from medium- and heavy-duty vehicles (EPA, 2020a). In addition, the transportation sector also contributes significantly to criteria air pollutant (CAP) emissions. According to the U.S. Environmental Protection Agency (EPA), in 2017, on-road

transportation contributed 29.5% to the national emission of nitrogen oxides (NO_x), which is a precursor of ground-level ozone formation and poses a serious public health risk in urban areas (EPA, 2017). Similarly, particulate matters (PM) are released from on-road vehicle operation. The PM are a mixture of solid particles and liquid droplets, having significant environmental and health hazard, e.g., causing lung and heart disease. Particularly, the PM with diameters less than 10 µm (PM₁₀) pose greater risks due to their ease of penetration to lungs (EPA, 2020b).

To reduce air emissions, electrification of the transportation sector with zero tailpipe emission vehicles is of increasing interest. Plug-in battery electric vehicles (BEVs) and hydrogen fuel cell electric vehicles (FCEVs) are two leading electrification technologies. Both BEV and FCEV have higher energy conversion efficiencies compared to internal combustion engine vehicles (ICEVs) powered by conventional gasoline. Lohse-Busch et al. conducted a laboratory test and demonstrated that a 2016 Toyota Mirai FCEV has an average powertrain efficiency of 62%, much higher than the 23% of ICEVs (Liu et al., 2020a; Lohse-Busch et al., 2020). A BEV powertrain is more efficient compared to FCEV, since BEV directly utilizes electricity from the battery to power the vehicle wheels, while FCEV needs to convert chemical energy in hydrogen to electricity in a fuel cell (Lee et al., 2018). According to www.fueleconomy.gov, a BEV has only a 15% to 20% energy loss (U.S. DOE, 2020). However, FCEV may be more cost effective compared to BEV, especially for medium- and heavy-duty vehicle applications where more onboard energy storage is needed.

Even though there are no direct tailpipe emissions from electric vehicles during on-road operation, the upstream processes to produce and distribute electricity and hydrogen might result in GHG and CAP emissions, depending on the production technology pathways and energy sources. Nuclear energy is of particular interest for both electricity and hydrogen production for BEV and FCEV applications, since it is a low-carbon energy source. Mining and purification of nuclear fuel, e.g., Uranium-235 (U-235), do consume fossil energy and emit fossil GHG, the contribution of which, however, is usually small. We conducted a full life cycle, or well-to-wheels (WTW) analysis to comprehensively assess the environmental performance of electric vehicles powered by nuclear-based electricity and hydrogen. The WTW emissions for BEV and FCEV are compared with those from conventional ICEVs powered by conventional gasoline.

The WTW analysis covers both well-to-pump (WTP) and pump-to-wheels (PTW) life cycle stages. For the case of BEV where the battery is recharged by nuclear-based electricity, the WTP life cycle includes stages such as uranium mining, enrichment, conversion, fabrication, and transportation to nuclear power plants (Wu et al., 2006). It also encompasses electricity generation via different nuclear reactor technologies, and transmission and distribution of electricity to the charging outlet. The PTW life cycle refers to the vehicle operation. Even though they have no direct evaporative and tailpipe emissions, BEV and FCEV produce minor PM emissions during on-road operation through brake and tire wear. Fig. 1 shows the system boundary of the WTW life cycle.

We utilized the Greenhouse gases, Regulated Emissions, and Energy use in Technologies (GREET[®]) model to conduct the WTW analysis (Wang et al., 2020a). The GREET model evaluates energy use and emissions for conventional transportation fuels (produced from oil refineries), conventional and emerging hydrogen production pathways (as will be discussed in the next sections), as well as regional and national electricity generation. The GREET model is updated annually to reflect both current industrial information and emerging technology status. For example, the emissions from electricity sector are updated annually based on reporting by Energy Information Administration (EIA) of the U.S. Department of Energy (DOE) (EIA, 2020).

The functional unit for WTW emissions is based on per vehicle kilometer (km) traveled. In this analysis, we focused only on the fuel cycle. The GHG emissions associated with the vehicle manufacturing cycle, including the manufacturing of engines, batteries and hydrogen fuel cells and carbon fiber tanks, has not been included, since their contribution to the total life cycle emissions (when amortized over the vehicle's lifetime driven kilometers) is small compared to the WTW emissions (Elgowainy et al., 2018; Liu et al., 2021). Similarly, the GHG emissions associated with the manufacturing of infrastructures, such as power plants and hydrogen production plants, has also not been considered in this analysis due to their even smaller impact (when amortized over total lifetime throughput of these plants). Several nuclear technologies to generate electricity are discussed below.

Fig. 1 The WTW system boundary of the BEV powered by nuclear electricity.

Overview of nuclear reactors

Nuclear fission is a process in which an atom splits into two or more smaller nuclei, while releasing energy in the form of heat. Two major types of nuclear reactor technologies are considered by the GREET model, namely, light water reactor (LWR) and future advanced high-temperature gas-cooled reactor (HTGR). According to the U.S. DOE Office of Nuclear Energy, all nuclear reactors operating commercially in the U.S. are LWRs (NUCLEAR 101, 2020), including both pressurized water reactors (PWR) and boiling water reactors (BWR); other reactor types are in commercial operation globally. More detailed description on these technologies can be found in other chapters of this encyclopedia, namely Brown (2021) for PWRs, Hamon (2021) for BWRs, and Fütterer (2021) for HTGRs. In contrast to LWRs, which uses ordinary water as both coolant and neutron moderator, HTGRs use a graphite moderator and helium as coolant (Wu et al., 2006; Breeze, 2019; Fütterer, 2021). Helium passes through the HTGR and carries away the heat released by the nuclear fission. The helium gas at high temperature flows through a heat exchanger to heat water for generating steam, which drives a steam turbine to provide shaft work to the power generator. Alternatively, the heated helium gas can directly drive a gas turbine to produce electricity, while the remaining heat can be used to produce steam for additional power generation or to export for other use. The HTGR has not yet been commercialized in the U.S., but it is included in this chapter for comparison with the LWR technologies in terms of life cycle emissions performance.

HTGRs require uranium fuels with a higher degree of enrichment compared to LWRs. HTGRs also have higher energy conversion efficiency since they can operate at high temperature (Wu et al., 2006; Breeze, 2019). From one gram of U-235, 31.3 GJ (8.7 MWh) of electricity can be generated using a HTGR, while a LWR may only generate 24.8 GJ (6.9 MWh) of electricity (Wu et al., 2006; Wang et al., 2020b). Details about the amount and share of energy sources required for the operation of nuclear reactors and the upstream production and transportation of uranium fuel are documented in Wu et al. (2006) and are already incorporated in the GREET model.

In the next section, we assess WTW GHG and CAP emissions of BEVs recharged with nuclear-based electricity, national and regional grid electricity mixes, and compare the results to those from conventional gasoline powered ICEVs.

WTW GHG emissions of BEV recharged by electricity from nuclear and other sources

In the current case, we assume that U.S. 2019 grid mix is used by all stationary processes in BEV's WTW analysis. The BEV operation stage can be powered by electricity from various sources, including nuclear power and national or regional grid electricity mix. The GREET model provides projections of future (i.e., 2035) electricity generation mix and emission factors (e.g., g CO₂ kWh⁻¹ electricity), based on EIA's Annual Energy Outlook (EIA, 2020). It also incorporates projected improvements in generation efficiencies based on literature data, which enables the estimation of the impacts of evolving technologies on WTW emissions. In this study, we consider two scenarios: the "current" scenario represents technology year of 2019 and the "future" scenario represents the technology year of 2035. For BEVs, we assume a battery charging efficiency of 85%.

Fig. 2 shows that for gasoline ICEV, over 80% of the WTW GHGs are emitted during the vehicle operation stage, i.e., when the gasoline is combusted in the engine. In contrast, BEVs do not produce GHG emissions during vehicle operation, with all their WTW GHG emissions occurring upstream, i.e., during the WTP stage. Fig. 2 also indicates that BEVs recharged by the current U.S. grid generation mix, which has a significant contribution from fossil power generation, has much lower WTW GHG emissions compared to gasoline ICEV. Clearly, the WTW GHG emissions of BEVs are highly dependent on the electricity generation fuel shares. BEVs

Fig. 2 WTW GHG emissions of gasoline ICEV and BEV recharged with electricity from various sources/technologies. The gram of CO₂ equivalent (CO_{2e}) is calculated using global warming potential (GWP) of CO₂, CH₄ and N₂O. The GWP of CO₂, CH₄ and N₂O is 1, 30, and 265, respectively.

recharged with nuclear-based electricity provide deep reductions in WTW GHG emissions, by 99% compared to gasoline vehicles and by 98% compared to BEVs powered by U.S. average grid generation mix. Among different nuclear technologies, PWR and BWR incur the same WTW emissions as provided by GREET 2020. The HTGR technology has slightly lower WTW GHG emissions compared to LWR technology due to its higher energy conversion efficiency, but the difference is negligible when the WTW results are calculated on a per-km basis.

In addition, Fig. 2 suggests that future U.S. average electricity generation mix for BEV recharging will provide deeper reduction in WTW GHG emissions compared to the current grid generation mix. Even though not 100% carbon-free, the nuclear technologies have the advantage of providing a steady electricity supply (with capacity factor of > 90%), when compared to solar photovoltaic (20–30% capacity factor) and wind power generation (30–40% capacity factor) (Liu et al., 2020b). We note that if all light-duty vehicles in the United States in 2019 (about 273 million vehicles) are electrified, the total annual electricity use for recharging these vehicles will be in the order of 1000 TWh. Similarly, if all medium- and heavy-duty vehicles in the United States in 2019 (about 12.7 million vehicles) are electrified, the total annual electricity use for recharging these vehicles will be in the order of 1200 TWh. To put this in context, the total annual generation capacity of nuclear power plants in the United States in 2019 was in the order of 850 TWh.

WTW CAP emissions of BEV recharged by electricity from nuclear and other sources

Fig. 3 shows that BEVs recharged by nuclear LWR technology emit only 4 mg NO_x per km traveled on a WTW basis, representing a 98% reduction compared to gasoline ICEVs that emit 159 mg NO_x per km. For gasoline ICEVs, approximately 47% (i.e., 75 mg km⁻¹) of the NO_x are emitted during the vehicle operation stage. This suggests that replacing gasoline ICEVs with BEVs in an urban driving setting can mitigate the public health concern caused by ground-level ozone formation, which utilizes NO_x as a precursor (Lee et al., 2018).

The emissions reduction potentials of BEVs recharged by nuclear-based electricity are significant for other CAPs as well. In terms of WTW PM₁₀ emissions (Fig. 4), BEVs recharged by nuclear LWR electricity emit 11 mg PM₁₀ per km traveled, representing over 50% reduction compared to gasoline ICEVs that emit 23 mg PM₁₀ per km. For both ICEVs and BEVs, the majority of the PM₁₀ emission occurs during the vehicle operation stage due to brake and tire wear. For ICEVs, the additional PM₁₀ emissions are emitted from tailpipe due to the combustion of gasoline in engine during vehicle operation. For BEV recharging using nuclear-based electricity, the contribution of the WTP life cycle to WTW PM₁₀ emission is negligible.

Impacts of regional electricity generation mix

The contiguous U.S. has eight major electricity regions according to North American Electric Reliability Corporation, and each region varies in shares of fuels use and electricity generation technologies. Fig. 5 shows the potential GHG emissions reduction benefits of BEVs powered by electricity generated from nuclear LWR technologies, compared to those powered by 2019 regional electricity generation mixes. The values in Fig. 5 indicate the ratio of WTW GHG emissions of BEVs powered by regional electricity generation mixes to those powered by electricity generated from nuclear LWR technologies. The higher value in a given region indicates a higher GHG emissions intensity associated with electricity generation mix in that region. Fig. 5 indicates that even if BEVs are recharged by the regional mix with the lowest carbon intensity, i.e., Northeast Power Coordinating Council or NPCC, they still emit 33 times more WTW GHGs compared to those recharged by nuclear power. This clearly shows the GHG reduction benefits of electrifying the transportation sector with nuclear-based electricity.

FCEV powered with H₂ produced from various technology pathways

FCEVs using hydrogen (H₂) as fuel provide another clean alternative to petroleum gasoline and diesel in transportation applications by producing zero tailpipe emissions. H₂ can be produced from a diverse range of energy sources and technology options, such as natural gas (NG) steam methane reforming (SMR), biomass gasification, and water electrolysis using electricity generated from various sources.

H₂ production technologies using various electricity sources

Nuclear energy can be utilized for producing hydrogen, with near-zero emissions (Knighton et al., 2020), as described in other chapters within this section (Suppiah, 2021; Boardman, 2021). In a centralized plant, H₂ can be produced via water electrolysis, which uses nuclear-based electricity to split water molecules into H₂ and oxygen (O₂). Additionally, H₂ can be produced via high temperature electrolysis in a solid oxide electrolyzer cell (HTE SOEC) using nuclear energy.

Alternatively, H₂ can be produced from low temperature electrolysis in a proton exchange membrane electrolyzer (LTE PEM) using nuclear-based electricity at refueling stations. The H₂ production using nuclear energy has significant environmental benefits relative to the current industrial hydrogen production via NG SMR.

In NG SMR, methane reacts with steam at high temperature and pressure in the presence of a catalyst to produce H₂ and carbon monoxide. This is followed by the “water-gas shift reaction,” where the carbon monoxide and steam react in the presence of a catalyst to produce carbon dioxide and additional H₂. Hydrogen is also co-produced at chlor-alkali plants that use an electrolysis process for splitting sodium chloride solution to produce chlorine and caustic soda, as well as H₂ gas as a byproduct.

To quantify the environmental benefits of FCEVs fueled by H₂ produced via electrolysis using nuclear-based electricity, the WTW GHG and CAP emissions are evaluated and compared to those from conventional ICEVs and FCEVs fueled by H₂ produced from other sources.

Fig. 6 depicts the WTW system boundary of the FCEV powered by H₂ produced from NG SMR and water electrolysis using electricity generated from various technologies, including nuclear LWR and HTGR. As with the assessment of BEVs, the technology year 2019 was selected in the current scenario and the technology year 2035 as future scenario. The WTW environmental impacts of the hydrogen FCEVs were evaluated in terms of their GHG and CAP emissions (e.g., PM₁₀ and NO_x) and compared to those from conventional gasoline ICEVs.

The WTW GHG and CAP emissions of electrolysis pathways for H₂ production depend strongly on fuel shares and generation technologies used for electricity generation. Therefore, the WTW emissions for FCEVs using H₂ produced via water electrolysis are evaluated for the following electricity generation sources: (1) electricity from nuclear power plants (nuclear electricity, as detailed in previous sections), (2) the current average U.S. grid generation mix (2019 U.S. grid mix), (3) future U.S. grid mix (2035), (4) current California grid mix (2019 CA mix), (5) future CA mix (2035), and (6) wind/solar electricity.

The production of H₂ can be centralized for large scale production to benefit from economies of scale, however, the H₂ product needs to be distributed and delivered to refueling stations, which consumes additional energy and generates air emissions. In contrast, H₂ can also be produced at refueling stations to reduce the energy use and cost associated with H₂ delivery, but this approach requires additional capital investment and land area at refueling sites. The emissions associated with H₂ delivery from central production sites to refueling stations are discussed below.

Gaseous and liquid hydrogen delivery pathways

In addition to its production, the delivery of H₂ plays an importation role in the overall WTW air emissions. Today, H₂ is delivered from central production sites to refueling stations by trucks in compressed gas or liquid product form. For gaseous H₂ (G.H₂) delivery, H₂ may be compressed to a pressure between 200 and 500 bar and loaded onto gaseous tube-trailers for transportation and distribution. The tube-trailer at a refueling station supplies H₂ to a gaseous compressor, which compresses it to 950–1000 bar and stores it in a high-pressure buffer storage system for dispensing into vehicle tanks at 700 bar. The hydrogen is typically precooled to –40 °C to avoid the overheating of vehicle tanks during fast refueling. The hydrogen packaging, delivery and refueling processes contribute to the WTW emissions of FCEVs (Liu et al., 2020). H₂ may also be liquefied, typically using liquid nitrogen to

Fig. 6 The WTW system boundary of the FCEV powered by H₂ produced from NG SMR and water electrolysis using electricity generated from various technologies.

precool the H_2 from ambient temperature to near 80 K, followed by a series of compression and expansion processes to reach 20 K, the temperature necessary for H_2 liquefaction near ambient pressure (Liu et al., 2020). Liquid hydrogen ($L.H_2$) is then stored in large cryogenic storage tanks at an adjacent distribution terminal, and subsequently loaded into cryogenic-liquid tankers for delivery to refueling stations. In general, $L.H_2$ delivery is more cost-effective compared to compressed $G.H_2$ delivery in tube-trailers, especially for long transportation distances, owing to its higher payload (4 vs. 1 metric ton). However, the H_2 liquefaction process is energy-intensive, consuming between 11 to 15 kWh of electricity per kg of H_2 , depending on H_2 supply pressure and the energy efficiency of the heat exchange, compression and expansion processes during liquefaction. Thus, the electricity used for liquefaction is an important element in the $L.H_2$ WTW analysis.

WTW air emissions of FCEVs using H_2 from various production and delivery pathways

For FCEVs, the only emission from the tailpipe is water vapor, so the WTW GHG and CAP emissions are mainly determined by the emissions from the upstream H_2 production and delivery activities. Table 1 shows the WTW GHG and CAP emissions for FCEVs using H_2 from 12 different production and delivery pathways and compares the results to those from gasoline ICEV.

The FCEVs with the highest WTW GHG emissions are those utilizing H_2 from fossil-fuel dependent pathways, namely NG SMR $G.H_2$ and $L.H_2$, as well as electrolysis pathways using current U.S. and CA grid mix. The WTW analysis considers emissions from the following stages: (1) H_2 production and its upstream processes (e.g., for SMR technology, the upstream processes include the natural gas recovery, processing, and transmission to hydrogen plant), (2) H_2 transportation and distribution from production sites to refueling stations, and (3) H_2 compression and precooling at refueling stations (only for $G.H_2$ delivery). We assume that compression and precooling of gaseous hydrogen at refueling stations sources electricity from the U.S. grid, and thus result in upstream (indirect) emissions from fossil power plants within the grid.

As seen in Fig. 7, FCEV using either $G.H_2$ or $L.H_2$ produced via HTE SOEC, exclusively sourcing nuclear energy, leads to lower WTW GHG emissions compared to other pathways. In contrast, FCEV using H_2 produced via LTE PEM using current U.S. grid mix electricity has the highest WTW GHG emissions, since over 60% of the current U.S. grid mix relies on fossil fuel sources, i.e., coal and NG (Wang et al., 2020a, b). Currently, H_2 is mainly produced from NG via SMR process. The FCEVs sourcing $L.H_2$ and $G.H_2$

Fig. 7 WTW GHG emissions of FCEVs using H_2 from various production technologies, compared with gasoline ICEV.

Fig. 8 WTW PM₁₀ emissions of FCEV using H₂ from various production technologies, compared with gasoline ICEV.

Fig. 9 WTW NO_x emissions of FCEVs using H₂ from various production technologies, compared with gasoline ICEV.

produced from the NG SMR pathway have WTW GHG emissions of 169 and 127 g CO_{2e} km⁻¹, respectively. If H₂ is liquefied via nuclear electricity, instead of U.S. mix, the WTW GHG emissions of FCEVs reduce from 169 to 105 g CO_{2e} km⁻¹. Evidently, the electricity source has a significant impact on the WTW GHG emissions of FCEVs when electricity is used for H₂ liquefaction and compression or when electrolysis sources electricity from the grid for hydrogen production. The NG SMR pathway with carbon capture and storage (CCS) has lower GHG emissions when compared to conventional NG SMR or water electrolysis with current or future U.S. and CA electricity grid mix.

The WTW GHG emissions of H₂ FCEVs are compared to gasoline ICEV, which has a WTW GHG emission of 254 g CO_{2e} km⁻¹, as shown in Fig. 7. The WTW GHG emission reduction potential of FCEVs relative to gasoline ICEVs depends strongly on the H₂ production and delivery technology pathway, and the carbon intensity of their energy sources. FCEVs powered by H₂ produced via water electrolysis using current U.S. grid mix has a WTW GHG emission of 250 g CO_{2e} km⁻¹, comparable to gasoline ICEV. In contrast, the FCEVs powered by H₂ produced via water electrolysis using nuclear and wind/solar electricity have the largest WTW GHG emissions reduction compared to gasoline ICEV.

Figs. 8 and 9 show the WTW PM₁₀ and NO_x emissions, respectively, for FCEVs using H₂ from various production and delivery pathways. As with WTW GHG emissions, FCEVs using H₂ produced from nuclear and wind/solar electricity-based water electrolysis produce the lowest WTW PM₁₀ and NO_x emissions. In general, all pathways that use a significant amount of grid electricity (e.g., for electrolysis and/or liquefaction) are associated with significant WTW NO_x and PM₁₀ emissions, consistent with share of fossil generation in the grid mix.

Conclusions

Using nuclear energy for either BEV (to supply electricity for battery recharging) or for FCEV (to produce H₂ for fuel cells) provides significant environmental benefits in terms of WTW air emissions reduction, particularly for GHG, PM₁₀ and NO_x. With power generation and transportation as the leading sectors for GHG emissions, nuclear energy can play an important role in the concerted effort to combat climate change via both near zero carbon electricity generation and near complete decarbonization of the transportation sector.

Glossary

COP Coefficient of performance, the ratio of the quantity of heat pumped from the cold temperature source to the hot temperature sink divided by the temperature difference between the source and the sink. The Carnot COP is the maximum COP and is: $COP_{Carnot} = \frac{T_H}{T_H - T_C}$ where T_H and T_C are the absolute temperatures in Kelvin (K) [Water freezes at 273 K and boils at 373 K when the pressure is 1 atm, 14.7 psi.]

HTHP High Temperature Heat Pump, defined as having a heat sink temperature $> 90^\circ\text{C}$.

Refrigerant (or Coolant) The fluid flowing through the heat pump system, generally as a liquid or a gas in various locations, that transfers heat from a heat source to a heat sink. In most of the instances described in this article the heat source is a lower temperature than the heat sink.

T_{Lift} Temperature difference between the sink and the source, $T_H - T_C$.

T_{Sink} For heat pumps in a heating mode, the output temperature, T_H For heat pumps in the cooling mode, the temperature at which heat is absorbed, T_C .

Introduction

Heat pumps are proof that, Joule for Joule, electricity is more valuable than heat from the point of a heat consumer. The best boilers have an efficiency around 90%, which means that they can turn 1 kWh of natural gas (heat content) into 0.9 kWh of useful heat. That same 1 kWh of heat from natural gas, burned in a turbine-generator, produces about 0.5 kWh of electricity. A heat pump can turn the 0.5 kWh of electricity into 2.5 kWh of useful heat (sometimes even more). This comparison, as well as several others included later in [Table 2](#), illustrates the importance of the Second Law of Thermodynamics in supplying heat to domestic and industrial processes, particularly at temperatures below 200°C ([Bienvenu, 2014](#)).

The need to severely constrain emissions of greenhouse gases in order to reduce climate change translates into a need to use carbon-free electricity for processes now heated by fossil fuels. Those processes include drying, cooking, pasteurization and other processes now commonly heated by the combustion of natural gas. A possible, though inefficient, heat source is resistance heating, such as the heating in an electric toaster. The thermal conversion efficiency (i.e., electrical energy divided by the thermal energy input) for most power plants, be they coal, natural gas, nuclear or wood heated, is generally between 30% and 60%. Therefore, the heat delivered to the product is only 30–60% of the energy of the fuel.

If the natural gas, coal or wood is used directly in the heating process, then in theory 100% of the energy in the fuel could be delivered to the process. In reality some heat is lost via the exhaust gases and to the ambient air surrounding the equipment.

But the temperatures in many industrial and commercial processes do not require the highest temperatures that can be attained via natural gas, coal or wood flames. A better solution in those cases is to use the high temperature flame to generate electricity, which in turn could operate a heat pump. Heat pumps can transfer heat from a low temperature, T_C , to a higher temperature, T_H , through the use of mechanical energy for compression. Today T_H is limited to about 140°C , though continuing research is raising that limit.

If the mechanical energy needed to drive the compressor is furnished by wind turbines, solar panels, hydro or nuclear, then the process heat can be delivered without the emission of greenhouse gases.

Theoretically heat pumps could deliver heat at very high temperatures, but the practical limitations of the working fluids (i.e., the “refrigerants”) limit the delivery temperatures to about 200°C . When the industrial processes require temperatures above 300°C , direct heat exchange with the reactor coolant, particularly helium from a Very High Temperature Reactor, is more advantageous.

Above about 1000 °C concentrating solar furnaces or the use of electricity via induction, arcs, microwaves or resistance heating is necessary.

It is often suggested that the heat of the reactor coolant could be used via a heat exchanger to supply the heat directly to the industrial processes. In those cases, tens or hundreds of megawatts could be supplied to a large facility such as a refinery, a chemical processing plant, a desalination plant or a hydrogen production facility using a thermochemical process (e.g., the sulfur-iodide or hybrid sulfur processes) (McMillan et al., 2016). Such industrial complexes would be large enough to host a dedicated reactor within their site. Serving several adjacent facilities might be feasible, though the long-distance transport of a high temperature gas, molten salt or liquid metal would require a substantial investment in the piping and pumping infrastructure. Furthermore, the possibility of radioactive contamination permeating through the heat exchanger and being carried in the intermediate coolant has to be carefully considered. In order to be economically feasible, the aggregate heat demands of the industrial complexes would have to be massive if the nuclear plant is dedicated to heat applications alone.

Heat pumps, especially High Temperature Heat Pumps (HTHPs) have the advantage of being able to serve demands in the kW to few MW range at locations remote from the reactor (or other generators, such as wind turbines or solar panels) with modest costs for added electrical distribution infrastructure. Heat pumps available today range in heating capacities from 20 kWth to 20 MW. In addition, concerns for the potential transport of radioactive contamination in the intermediate coolant are avoided through the use of electrical transmission.

Often, the low temperature (i.e., T_C) heat source can be waste heat that is typically vented to the atmosphere as exhaust steam, exhaust air from industrial processes and cooling of products. In fact, some installations use heat pumps to supply both air conditioning and domestic hot water, using the heat rejected by the air conditioner as the heat source for water heating. Some more elaborate installations in supermarkets supply hot water and building heat while cooling freezers and fresh product cabinets. These systems have to be flexible to accommodate changing seasons, product arrangements and customer traffic.

The largest market today for heat pumps is for building heating and air conditioning. In the heating mode the heat source is the outside air ($-15\text{ }^{\circ}\text{C}$ to $15\text{ }^{\circ}\text{C}$) or groundwater ($5\text{ }^{\circ}\text{C}$ – $20\text{ }^{\circ}\text{C}$) while the heat sink is the room temperature of the building or home ($20\text{ }^{\circ}\text{C}$ – $25\text{ }^{\circ}\text{C}$). In the cooling mode the heat source is the building interior ($20\text{ }^{\circ}\text{C}$ – $25\text{ }^{\circ}\text{C}$) while the heat sink can be summer outside air ($30\text{ }^{\circ}\text{C}$ – $45\text{ }^{\circ}\text{C}$) or groundwater which remains ($15\text{ }^{\circ}\text{C}$ – $25\text{ }^{\circ}\text{C}$). The global heat pump market surpassed USD 48 billion in 2019 and annual sales are anticipated to exceed 16 million units by 2026 (GMInsights, 2020).

The operation of a heat pump

The operation of a heat pump such as that depicted in Fig. 1 is shown for a two-phase coolant in Fig. 2. The pressure of the coolant is on the vertical axis and the specific volume (m^3/kg) is shown on the horizontal axis. The points 1 through 4 in Fig. 1 correspond to the conditions at points 1–4 on the p, V diagram in Fig. 2. Beginning at point 1, the mixture of liquid and vapor is boiled in the evaporator at a constant temperature, T_C , to a completely vaporous state at point 2, the top of the evaporator in Fig. 1. The vapor is then compressed to a higher pressure by the compressor and is slightly superheated (i.e., is above the boiling temperature for the hot temperature, T_H) at point 3. Because of the compression, the coolant condenses at a higher temperature, T_H , between points 3 and 4, and delivers useful heat to a process, such as those shown in Tables 1 and 2. The cycle is completed when the high-pressure liquid

Table 1 US process heat demand for which HTHPs might be used.

2008 Process heat demand ($PJ_{th} = 10^{15} J_{th}$)				
Process	40 °C–80 °C	80 °C–120 °C	120 °C–160 °C	160 °C–200 °C
Paper and pulp			1050	180
Chemicals			420	630
Food industry	230	180	60	100
Primary metals				140
Other manufacturing	15	30	220	150

The total demand in these industries equals 3416 PJ_{th} , resulting in the emission of 170 million t of CO_2 if supplied by natural gas.

Adapted from Arpagaus C, Bless F, Uhlmann M, Schiffmann J and Bertsch S (2018) High temperature heat pumps: Market overview, state of the art, research status, refrigerants, and application potentials. In: *International Refrigeration and Air Conditioning Conference, Paper 1876*. <https://docs.lib.purdue.edu/iracc/1876> (Accessed on 23 January, 2021).

flows through an expansion (throttling) valve between points 4 and 1 of Fig. 1, exiting as a liquid-vapor mixture at the lower evaporator pressure. Heat does not flow effortlessly from a low temperature to a higher temperature; the mechanical energy exerted in the compressor pumps the heat.

The relationship between the amount of heat pumped up to the higher temperature to the mechanical work done in the compressor is known as the Coefficient of Performance, COP. For a perfect, isentropic (i.e., Carnot) cycle COP is given by

$$COP = \frac{T_H}{(T_H - T_C)}$$

where both T_H and T_C are absolute temperatures (i.e., the number of degrees above absolute zero).

Currently available high temperature heat pumps

Arpagaus et al. (2018) compared the COP values for about 35 industrial HTHP systems for a range of temperature lifts ($T_{lift} = T_H - T_C$) supplying heat at 140 °C, here labeled T_{sink} . As shown in Fig. 3, nearly all of the HTHPs had COP values between 30% and 60% of the Carnot COP, the theoretical maximum.

Comparisons of simple HTHP applications

In Fig. 4, the curves for the Carnot Coefficient of Performance, the theoretical maximum, and for various fractions of COP_{Carnot} from 30% to 60% are plotted. Based on the performance shown, we can estimate the performance of HTHPs in various situations.

Nine different configurations using an arbitrary amount of fuel (here, 1 GJ_{th}) are shown in Table 2. The amount of fuel used has no effect on the comparisons; the ratios remain the same. Example 1 is a natural gas burner in a food processing plant cooking

Table 2 Comparisons of the impact of HTHPs on energy efficiency and CO₂ emissions.

Example	Fuel	Customer	Technology	Generation efficiency	T_{cold} [°C]	T_{hot} [°C]	T_{lift} [K]	% of carnot	COP	Delivered heat [GJ _{th}]	CO ₂ per GJ _{th} delivered [kg]
1	NG (48 MJ/kg)	Food processing	Gas range	97%	n.a.	110	n.a.	n.a.	1.00	0.97	709
2	NG	Electric range	Combined cycle	60%	n.a.	110	n.a.	n.a.	1.00	0.60	1146
3	NG	Food processing	Steam turbine	38%	35	110	75	60%	3.06	1.16	590
4	NG	Food processing	Combined cycle	60%	35	110	75	60%	3.06	1.84	374
5	NG	Hot water	Steam turbine	38%	35	70	35	60%	5.88	2.23	308
6	NG	AC/hot water	Combined cycle	60%	20	70	50	60%	4.12	2.47	278
7	Nuclear	Food processing	Steam turbine	32%	35	110	75	60%	3.06	0.98	0
8	Nuclear	Cooking/ freezing	Steam turbine	32%	−10	80	90	60%	2.35	0.75	0
9	Nuclear	Distillation	VHTR	45%	60	160	100	60%	2.60	1.17	0

**Fig. 3** COP as a function of the temperature lift for various industrial HTHPs. a stew. In this case, assume that most of the heat (97%) from the flame is delivered to the water. Example 2 is an electric range using electricity from a natural gas fired combined cycle plant where the electrical generating efficiency is 60%, the highest efficiency presently achievable. Despite that high efficiency only 60% of the fuel's combustion energy is delivered to the boiling water.

Example 3 considers a food processing plant preparing the same stew considered in Example 1. that also requires boiling water. The electricity is generated in an older plant via a steam turbine with an efficiency of 38%. The food processing plant has a high temperature heat pump that draws heat from a waste heat source (e.g., hot air exiting the plant) at 35 °C and pumps that heat up to 110 °C. In this

case the COP is slightly above 3.0, 60% of the theoretical maximum (i.e., Carnot) efficiency. In this example the HTHP provides 1.16 times more heat to the boiling water than would be furnished by the natural gas. In Example 4 we see the effect of more efficient combined cycle turbines, allowing the HTHP to provide 1.84 times more heat to the stew than would be provided by the natural gas.

Process heat is needed at different temperatures to meet various needs. In Example 5, the HTHP draws heat from a low temperature source (e.g., exhaust air) to heat water to 70 °C for washing. Even though the electricity is derived from a less efficient plant, the HTHP can deliver 2.23 times the heat of the initial natural gas combustion because of the lower output temperature. Example 6 shows a combination of air conditioning and domestic hot water heating, drawing heat from the living or working spaces at 20 °C and delivering heat to the water at 70 °C. In Example 6 the HTHP provides a service at both ends of the cycle.

Examples 7–9 track the cycles powered by 1 GJ_{th} of heat from nuclear fuel. The nuclear plant is assumed to be a Light Water Reactor producing saturated steam and having a typical generating efficiency of 32%. The industrial process is that of Example 3, but the lower generating efficiency decreases the delivered heat, though it is still nearly equal to the fuel input.

In Example 8, we see another dual-purpose cycle, providing heat for a cooking step at 80 °C and drawing the heat from a freezer at –10 °C. Finally, Example 9 tracks the performance of a cycle driven by a Very High Temperature Reactor, operating at about 800 °C and cooled by helium gas. The HTHP delivers heat at 160 °C to a distillation process while drawing its heat from a waste source at 60 °C.

The nine relatively simple examples show the flexibility and effectiveness of cycles incorporating HTHPs, pumping heat from low temperature locations where it is not wanted or is going to waste and delivering heat at the higher temperatures needed.

Requirements for refrigerants/coolants

The more important component of a heat pump or refrigeration system is the refrigerant that flows from the evaporator through the compressor to the condenser thence through the throttling valve to complete the cycle. These fluids are generally known as refrigerants even when the purpose of the cycle is to pump heat to a higher temperature.

In order to have an efficient cycle and a reasonably sized condenser and evaporator, it is generally necessary for the refrigerant to be a two-phase mixture for both the condenser and evaporator pressures and temperatures. That requirement then implies that the output temperature cannot be higher than the critical temperature, T_{crit} , for a particular refrigerant. Recall from Fig. 2 that T_{crit} is at the top of the two-phase “dome” in which the cycle operates. The top of the dome also corresponds to the critical pressure. Operating at very high pressures in order to approach T_{crit} poses challenge for design of the compressor, piping, valves and gaskets. Table 3 lists the characteristics of refrigerants suitable for HTHP applications. (Z) and (E) indicate *cis*- and *trans*-isomers respectively.

The next set of refrigerant characteristics concern the consequences of releasing the fluids into the atmosphere. Early refrigeration cycles used ammonia (NH₃), but its accidental release resulted in injuries and death to those caught in the plume. Less toxic refrigerants, the chlorofluorocarbons (CFCs) and the hydrochlorofluorocarbons (HCFCs), were developed in the 1920s as both refrigerants (Freon) and as fire extinguishing agents (Halon).

Beginning in the 1960s, CFCs and HCFCs were found to be depleting the atmospheric ozone layer that protects the surface of the earth from ultraviolet light coming from the sun. The Montreal Protocol of 1987 phased out the use of chemicals known to be depleting the ozone.

Table 3 Refrigerants suitable for HTHP applications.

Type	Refrigerant	Chemical formula	T_{crit} [°C]	p_{crit} [MPa]	Ozone depletion potential [–]	Global warming potential Myhre et al. (2013) [–]	Safety group ASHRAE (2016)	Normal boiling point [°C]	Mole-cular weight [g/mol]

Adapted from Arpagaus C, Bless F, Uhlmann M, et al. (2018) High temperature heat pump using HFO and HCFO refrigerants—System design, simulation, and first experimental results. In: International Refrigeration and Air Conditioning Conference, Paper 2199, <https://docs.lib.purdue.edu/iracc/2199> (Accessed on 23 January, 2021).

The hydrofluoroolefins (HFOs) and hydrochlorofluoroolefins (HCFOs) were developed as the next generation of refrigerants, though the HCFOs have small Ozone Depletion Potential (ODP) values.

Some refrigerants are strong greenhouse gases, trapping infrared radiation within the atmosphere. The values of the Global Warming Potential (GWP) for various refrigerants are based on a 100-year time horizon setting $\text{CO}_2 = 1.0$ (Myhre et al., 2013). The toxicity of the refrigerants is according to the safety groups of ASHRAE (formed at the American Society of Heating, Refrigerating and Air-Conditioning Engineers). The groups are A1: (Lower Toxicity, No Flame Propagation), A2: (Lower toxicity, Lower Flammability) and A3: (Lower Toxicity, High Flammability).

There is continuing interest in H_2O and CO_2 as refrigerants because of the abundance and low toxicity/flammability. Water has the potential for reaching higher temperatures, albeit at very high pressures (Wang et al., 2010), and carbon dioxide has been demonstrated in an integrated supermarket system in Italy (Azzolin et al., 2018).

The economics of heat pump operation

Space and water heating represent about 80% of the final energy use in the European domestic sector; thus, heat pumps represent attractive methods for decarbonization (Barnes and Bhagavathy, 2020). However, the relatively high taxes on electricity compared with those on natural gas presently have the unintended effect of discouraging investment in heat pumps. Worldwide, only about 5% of residential heat demand was met using heat pumps in 2019, though in the United States more than 40% of new single-family dwellings and nearly 50% of new multi-family buildings utilize heat pumps (IEA, 2020). Sales of heat pump water heaters have tripled since 2010, primarily due to efforts in northern China to improve air quality through the replacement of coal-fired boilers.

For the decarbonization of large scale industrial processes, Zühlsdorf et al. (2019) considered reversed Brayton cycles and steam compression, allowing delivery temperatures of 280 °C. The analysts reviewed a wide range of processes including lumber and paper drying, petroleum refining, preheating, and digesting bauxite slurry for aluminum production and spray drying in the food industry. The various HTHP cycles were evaluated on the basis of capital costs and with a tax on CO_2 emissions of 50€/t. If the electricity is supplied from zero carbon sources, the HTHP systems are more economical than the present use of natural gas for direct heating.

On-going research projects

In order to make heat pumps and especially HTHPs relevant to both residential and industrial needs in a carbon-constrained world, research is being pursued in many countries. Korea, China, Japan, Switzerland and The Netherlands are leading the experimental research on HTHPs, with the main research goals being to improve heat pump efficiency, testing laboratory functional models from 1.8 to 12 kW. Some larger prototypes are capable of producing several hundred kW of heat. Laboratory systems primarily use piston compressors (Arpagaus et al., 2016, 2018).

Technical barriers to wider market penetration include a lack of high temperature refrigerants with low Global Warming Potentials and a lack of demonstration facilities. On the marketing side there is a lack of understanding of the HTHP technology among consultants, designers, producers and installers. Furthermore, there is a lack of knowledge about the integration of HTHPs in industrial processes. Finally, low fossil energy prices foster competing technologies, despite the carbon footprint.

Introduction

The modern world was made possible by low-cost, easy-to-store, easy-to-transport fossil fuels. Fossil fuels enabled billions of people to move to the middle class. The capital costs of fossil power plants, furnaces, and other power conversion systems are low relative to the cost of fossil fuels, and the cost of fossil fuel storage is low. These two characteristics make it economic to operate these systems at part load to economically provide variable electricity, mechanical work and heat to the customer, and they enable economic integration into an electricity grid that has medium quantities of high-capital-cost low-operating-cost nuclear, wind and solar power plants. Alternately, operating nuclear, wind and solar plants at half their capacity approximately doubles the cost of energy. Utilization of fossil fuel plants to support peak energy demands enables economic operation of nuclear and renewable technologies at full capacity while meeting the need for variable electricity.

The world is undergoing massive changes in energy markets in response to a long-term goal of a low-carbon economy with limited to no carbon dioxide emissions to the atmosphere. Reaching that goal requires implementation of carbon capture and sequestration (CCS) approaches or replacement of fossil fuels in providing variable electricity and heat to match customer demands. Recent studies (Sepulveda et al., 2018) show that (1) the lowest-cost low-carbon systems include some combination of dispatchable (nuclear) and non-dispatchable (wind and solar photovoltaic (PV)) energy sources and (2) the lack of very low-cost energy storage is a major factor in higher energy costs of low-carbon systems. To economically match production with demand requires very low-cost methods to store energy. There are three classes of storage technologies: (1) work (electricity) storage: batteries, hydro pumped storage, etc.; (2) heat storage; and (3) chemical storage (hydrogen, etc.). Electricity storage best couples to the electricity grid and electricity generating technologies such as wind and solar PV. Heat storage technologies best couple to heat generating technologies such as nuclear, concentrated solar power (CSP), fossil fuel plants with CCS, and geothermal. Hydrogen storage couples to different hydrogen production technologies.

Heat storage is much less expensive than electricity storage because low-cost materials (crushed rock, liquid salts, etc.) are used. However, to date, its deployment in large systems has been limited to CSP plants. Historically that situation has been because it is inexpensive to store fossil fuels and burn them to produce heat, obviating the need for large-scale heat storage. That situation is changing. First, the goal of a low-carbon energy system requires energy storage to replace the role of fossil fuel storage in providing variable energy. Second, the deployment of significant capacity of non-dispatchable wind and solar PV has created periods of low and high electricity prices. This creates economic incentives for nuclear reactors that produce heat to include heat storage to enable selling more electricity at times of high electricity prices (high demand) and less electricity at times of low electricity prices (low demand).

This chapter first describes energy systems that incorporate heat storage to enable variable electricity and heat production with the reactor operating at baseload—the most economic mode of operation. The three components of heat storage systems are then described: (1) transferring heat from the reactor to storage, (2) heat storage, and (3) conversion of stored heat to electricity. Last, the integration of hydrogen production and storage into nuclear systems with heat storage and electricity production is described. Low-carbon nuclear hydrogen production technologies require heat and electricity, creating large economic incentives to couple heat storage with hydrogen production.

Heat storage systems

The nuclear heat storage system is shown in Fig. 1 to address hourly to seasonal needs for variable energy. The same system design can be used for any heat generating technology. To minimize the cost of energy, the reactor operates at full capacity. When electricity demand is high, resulting in high prices, reactor heat is sent to the turbine to produce electricity. When demand is low, resulting in low electricity prices, a majority of the heat is diverted to heat storage. During peak demand that exceeds the baseload reactor electricity output, combined heat from the reactor and heat storage is sent to the turbine-generator for electricity production, supported by either oversizing the turbine generator or building a separate peaking turbine-generator for peak power output. At times of very low (or negative) electricity prices, grid electricity can be converted into stored heat using resistance heaters coupled to the heat storage system. Hence, the power plant system can both sell and buy electricity. If stored heat is insufficient to meet peak demand, combustion of natural gas or low-carbon biofuels and hydrogen can provide heat to support peak electricity production.

The system design shown in Fig. 1 enables economic larger-scale use of wind and PV by several mechanisms. The large-scale addition of wind and PV in countries such as Germany and Denmark as well as states such as California has resulted in increased electricity prices (Bushnell and Novan, 2018). Large amounts of wind and PV collapse the price of electricity at times of high output and low demand, thus collapsing revenue. Some type of subsidy is required to compensate for revenue collapse. Second, added generating capacity is needed for times of low wind and solar production. In grids having only wind and solar generation, batteries or pumped hydro provides backup to wind and solar. These storage systems can be depleted and thus must be backed up with a gas turbine or equivalent generating technology. The stacked cost of assured generating capacity (wind or PV + batteries + gas turbine) is what makes systems with large quantities of wind and solar PV expensive (Sepulveda et al., 2018). The nuclear heat storage system addresses both challenges.

- **Storage.** Low-cost storage provides a sink for excess wind and solar PV production and sets a minimum price for electricity. There are two factors that enable low cost storage. First, today the cost of heat storage per unit of electricity is a factor of three to four less than storing electricity and in the future may be more than an order of magnitude less than electricity (EPRI, 2017). Unlike electricity storage technologies, relatively little work has been done to develop large-scale heat storage systems. Second, the cost of converting electricity to stored heat is much lower than any other system. Deployment of large-scale wind or solar results in times where some wind and solar is shut down when production exceeds demand. This creates large economic incentives to find ways to store this excess energy. To sell electricity the power plant has switchgear, transformers, and grid connections. The same equipment is used to import electricity into the plant for conversion into heat at no added cost.
- **Generating capacity.** In the above system, if the generating capacity equals peak demand, one can assure meeting electricity demand—no stack of generating technologies is needed to provide assured capacity. A low-cost combustion burner (rather than a more expensive gas turbine) provides the assured peak generating capacity. The fuel would be natural gas or low-carbon hydrogen or biofuels.

The minimum-cost system depends upon (1) the capital and operating costs of nuclear, heat storage, wind, and solar, (2) the quality of local wind and solar resources, and (3) the heat and electricity demand on an hourly to seasonal basis. The optimum ratios of installed capacities of each generating technology depends upon local conditions. If a particular market has a high demand for air conditioning that matches solar output, the optimal system design will support higher PV capacity. If there is a large demand for industrial heat, this will favor installation of thermal generators, such as nuclear systems. Nuclear reactors produce heat. The laws of thermodynamics (Carnot cycle) implies several units of heat are required to make a unit of electricity. Consequently, nuclear reactors produce low cost heat and more expensive electricity. Electricity can be converted to heat using resistance heating resulting in

Fig. 1 Base-load nuclear, wind and solar with heat storage to provide variable heat, electricity and hydrogen.

one unit of electricity producing one unit of heat. Wind and solar PV produce electricity that results in expensive heat. If everything else is equal, the different conversion efficiencies of heat-to-electricity versus electricity-to-heat favor heat-generating technologies if the customer needs heat and electricity-generating technologies if the customer needs electricity. Today fossil systems are very similar worldwide. The relative amounts of nuclear, wind, solar and heat storage will vary with location.

The system in Fig. 1 can also be used for cogeneration of electricity and heat. Cogeneration has significant implications for the electricity grid because it directly links the industrial heat market to electricity markets. Some industrial processes can operate flexibly or vary heat demand, freeing up heat for electricity production when needed and consuming added heat at times of low electricity demand. Coupling the industrial sector with the electricity sector via storage adds another dimension to balancing energy production with demand.

As discussed in other chapters (see Suppiah, 2021; Boardman, 2021), energy can be stored in the form of hydrogen. One option is to store hydrogen underground in the same facilities used for seasonal natural gas storage; thus, enabling seasonal storage of energy in the form of hydrogen. As described later, there is a large and growing industrial demand for hydrogen, and it can also be used as a low-carbon replacement fuel for fossil fuels. The leading candidate for nuclear hydrogen production is high-temperature (steam) electrolysis (HTE) of water (Pinsky et al., 2020)—a process that requires heat and electricity (see Suppiah, 2021). Hydrogen production facilities are capital intensive, not just due to the production process but also the compressors, pipelines, and associated facilities—all with large economics of scale. Hence, it is uneconomic to operate such facilities at low capacity factors. This may require that plants producing hydrogen operate more than 80% of the time (Boardman et al., 2019). The HTE plant can be embedded into a system that includes nuclear and renewable generators and heat storage (Fig. 1). At times of low electricity prices, electricity from the grid, or electricity produced by the nuclear reactor, can be used for HTE while heat from the nuclear plant is directed to storage and the HTE plant for hydrogen production. At times of high electricity prices, heat from the reactor and heat storage produce peak electricity with no hydrogen production.

This nuclear heat-storage hydrogen system has three key characteristics. First, because large-scale hydrogen storage is inexpensive using natural-gas storage technologies, stopping hydrogen production does not disrupt hydrogen supply to the customer. Second, the system design allows low-value wind and solar electricity, when available, combined with heat from the nuclear reactor to produce higher-value hydrogen. Any excess heat from the nuclear plant is directed to lower-cost heat storage for later use. Capital-intensive nuclear, wind, solar, and hydrogen facilities are fully utilized. Third, it enables the nuclear plant to operate at full capacity, producing peak electricity 20% of the time and hydrogen for as much as 80% of the time. The capital cost of hydrogen production facilities is high; thus, economic operation of the hydrogen plant requires high capacity factors (Lucid Catalyst, 2020). This enables the nuclear plant to economically address seasonal peaks in electricity demand that total a hundred to a thousand hours per year.

There are many heat storage technologies that can be incorporated into the described system (Forsberg, 2019; Forsberg et al., 2019, 2020b). At present, all of the large-scale commercially-deployed heat storage technologies were developed for concentrated solar power (CSP) systems, but their characteristics make them suitable to nuclear integration as well. The largest CSP systems store heat in liquid nitrate salts where the temperature varies from 285 to 565 °C. In these systems (Fig. 2) cold nitrate salts enter the CSP system, are heated in tubes exposed to concentrated sunlight, and are sent to the hot-salt storage tank. Hot nitrate salt is sent to steam generators where water is converted into steam to drive the power cycle. The resulting cold salt is sent to the cold-salt storage tank, and ultimately back to the CSP system to be reheated. In large CSP systems, the heat storage capacity is several gigawatt hours (GWhs).

Fig. 2 System design for CSP and nuclear with heat storage.

Storage accomplishes several functions. Peak electricity output is separated from the heat generating system and sized to match market needs. The peak electricity output may be much larger than the maximum output of the heat generating technology. Second, incorporation of energy storage simplifies operations. On partly cloudy days, the power output of a CSP system varies depending upon whether the clouds are blocking the sun. Without heat storage the power output would go rapidly up and down with changing cloud cover. In the nuclear plant, the reactor can operate at steady state independent of variable demand for electricity or any electricity grid disturbances.

Nuclear reactor heat to heat storage and power cycles

In a typical storage system, such as a pumped-hydro-electricity facility, there are losses associated with pumping the water uphill and losses when the water goes through the turbine. As a consequence, the round-trip efficiency is 75–80%; that is, for every kWh of electricity going into the pumped-hydro system, 0.75–0.85 kWh of electricity is sent back to the grid. These losses may or may not exist for heat storage systems. In the above CSP example (Fig. 2), the nitrate salt is heated and sent directly to storage. There is no temperature loss across a heat exchanger. There are minimal losses in going from storage to the power cycle—the power cycle does not know if the nitrate salt came from the CSP system or heat storage. There are heat losses during storage through the tank insulation, but these are typically 1–2% per day. The round-trip efficiencies in such heat storage systems can be greater than 95%, which is significantly better than batteries or pumped hydro facilities.

The same strategy can be used for some but not all storage systems coupled to a nuclear reactor. Many reactors require intermediate heat transfer loops to separate the low-pressure reactor from the high-pressure power cycle. Most designs of salt-cooled reactors now propose (Forsberg et al., 2020a, b; Forsberg, 2020) to use a nitrate-salt intermediate loop that can support heat storage—the same technology used in CSP plants. Nitrate loops achieve three purposes: separate the high-pressure power cycle from the low-pressure reactor, heat storage, and trapping of tritium. Many of these reactors produce tritium that can escape via the power cycle. If tritium diffuses through the heat exchangers into the power cycle, the tritium is oxidized, converted to tritiated water, and removed from the nitrate off-gas as steam. Intermediate nitrate salt loops are also proposed for some sodium fast reactors and for advanced fusion reactors with salt blankets. In these systems (Forsberg et al., 2020b) heat storage completely decouples the reactor from the power system, having multiple implications:

- The peak power output is independent of the reactor output.
- Multiple turbines may be used, where one turbine is designed to operate most of the time and is designed for high heat-to-electricity efficiency and a second turbine is designed as a peaking turbine with somewhat lower efficiency but lower capital costs.
- The power cycle is separated from the reactor without the constraints imposed by coupling the reactor and turbine. The turbine can be built to non-nuclear commercial standards and be on automatic control by the grid operators because the reactor does not “see” any transients from the operation of the turbine.

Heat storage can also be incorporated into the power cycle rather than between the reactor and the power cycle. Westinghouse and others have been examining heat storage coupled to light water reactors (LWRs) with peak power obtained by oversizing the main turbine generator. In this system, the electricity output may vary from 30 to 130% of baseload output. At times of low electricity demand, high-temperature steam transfers its heat through a heat exchanger to a heat-transfer oil. These oils are stable to temperatures up to 400 °C at atmospheric pressure. Peak LWR temperatures are about 300 °C. Heat transfer oils have been used in the chemical industry for almost a century and are used in lower-temperature CSP systems. The hot oil transfers its heat to high-temperature concrete, crushed rock or another low-cost storage material. This design minimizes the inventory of the more expensive heat transfer oil. The process is reversed to send steam back to the power cycle. Round trip efficiencies up to 80% (Amuda and Field, 2020; Kluba and Field, 2019) are possible, implying that the electricity produced from heat in storage is 80% of the electricity that would have been produced sending steam directly to the turbine generator.

Because of temperature losses in the heat storage cycle, steam returning from storage is at a lower temperature than the steam sent to storage. In an LWR saturated steam cycle under normal operations, steam is sent through multiple turbines with up to one third of the steam extracted from the turbines at different temperatures to heat feedwater. Cold feedwater from the condenser is heated by multiple feedwater heaters before entering the steam generator in a pressurized water reactor or returned to the reactor in a boiling water reactor. Preheating cold feedwater improves steam cycle efficiency. Lower-temperature steam from storage matches the temperatures of steam extracted from the steam turbine and can be used in the feedwater heating system. Reducing steam extraction from the turbines for feedwater heating increases the power of the turbine, producing peak electricity.

Heat storage technologies

Many heat storage technologies are under development for nuclear and CSP systems, but only a few have been commercially deployed at scale in CSP systems. Two recent workshops (Forsberg, 2019; Forsberg et al., 2019) summarize the current status of different systems for nuclear applications. Heat can be stored as sensible heat, latent heat, and in chemical systems. All commercial large-scale systems use sensible heat because of its lower capital costs.

There is no single heat storage system that will optimally meet all needs. Different reactor types operate at different temperatures; thus, only some heat storage systems couple to specific reactors. Second, the optimum system depends upon the specific market. If a nuclear reactor is in a utility system with excess electricity produced during the day, the economics will favor systems with daily storage. If a nuclear reactor is in a system where there are large weekday/weekend variations in demand, another storage technology may be preferred that has a somewhat lower capital cost per unit of heat storage capacity but with a lower round-trip efficiency. If a heat storage system is used daily, the storage system earns revenue 365 days per year. If a heat storage system is used once a week, the storage system earns revenue 52 times per year. The economics requires that heat storage systems used fewer times per year have much lower capital costs. In practice, this results in using heat storage systems that may be less efficient for long-term storage if their capital costs are much less. Several leading candidates are described below.

Liquid salts

The primary heat storage materials used in high-temperature CSP systems are nitrate salts, with solar salt (60 wt% NaNO_3 –40 wt% KNO_3) being the most common salt. Sensible heat storage is typically obtained by varying temperatures from 290 to 565 °C. With control of gas compositions over the salt storage tanks and control of the salt chemistry, salt storage temperatures of 600 °C may be viable. These salts are chemically stable in air. Heat storage system capital costs in CSP systems are ~\$20/kWh of heat. The largest CSP deployed storage system sizes are measured in gigawatt-hours of capacity. Nitrate-salt intermediate-heat-transfer loops are currently proposed for Sodium Fast Reactors (SFRs), Fluoride-salt-cooled High-Temperature Reactors (FHRs) with solid fuel and clean salt, thermal-spectrum molten salt reactors (MSRs) with fuel dissolved in the salt, and fusion machines with salt blankets. Different companies either include heat storage in the baseline design or as an option: SFRs (TerraPower), FHRs (Kairos Power), and MSRs (Moltex, others). Nitrate salts can also be used to move heat to industrial customers at higher temperatures than heat transfer oils but has not been commercially deployed.

Work is underway (Mehos et al., 2017) to develop second generation salt systems that would allow CSP systems to operate at peak temperatures of ~750 °C with higher-temperature stored heat. The goal is to have a pilot plant by 2025. The proposed salt is a sodium, potassium, magnesium chloride eutectic with a melting point of 383 °C. This salt was chosen because of its extremely low cost combined with reasonable physical properties. Allowable peak operating temperatures could exceed 1000 °C. The very low cost is because of (1) the low cost of the raw materials and (2) a potassium magnesium salt that is used in the large-scale production of magnesium. Hence, there is an industrial supply chain. There are two challenges: proper control of chemistry to minimize corrosion and development of a low-cost reliable tank insulation system. In a nitrate salt storage tank, relatively low-cost steels can be used so the tank insulation is on the outside of the tank. At much higher temperatures the low-cost storage option is to put the insulation on the inside of the storage tank so low-cost steels operating at lower temperatures can be used in large tanks. Ceramic insulation is used on the inside of salt storage tanks in industry, but it is not available at the sizes required for heat storage. Chloride salt storage is proposed to be used with molten chloride fast reactors with reactor peak temperatures near 750 °C. The chloride storage salts would also couple to higher-temperature HTGRs.

Heat transfer oils

Lower-temperature CSP systems use heat transfer oils, such as Therminol-66[®]. These systems have operating temperatures below 400 °C—the upper temperature limit for these oils. These heat storage systems are compatible with existing LWRs with peak temperatures of ~300 °C. These oils are stable, well understood, low vapor pressure to minimize fire hazards and over 50 years of industrial experience. Their major drawback is their cost when used for heat storage; thus, the incentive to couple with a lower cost storage material such as concrete or crushed rock.

Crushed rock and concrete

The costs of liquid salt and heat-transfer oil heat storage systems can be reduced with the use of a lower-cost filler material. Both crushed rock and special high-temperature concretes are being considered. Concrete can be formed into specific shapes such as monoliths with narrow channels to minimize the inventory of heat transfer fluid. Crushed rock is the lowest-cost fill material but has a higher void volume.

The existing CSP systems with hot and cold tanks of nitrate salts or oils can be viewed as first-generation heat storage systems. The second generation systems under development fill the storage tanks with lower-cost solid materials. Westinghouse is examining a system for LWRs where steam is used to heat oil that, in turn, transfers its heat to concrete in prefabricated boxes filled with closely packed concrete plates with small cooling channels between the plates (Forsberg, 2019). This design minimizes the inventory of the more expensive heat transfer oil. At times of high electricity demand, the oil transfers heat back to the steam cycle as described above.

Korea (Amuda and Field, 2020; Kluba and Field, 2019) is examining a similar system for LWRs that uses crushed rock as the heat storage material. The design would include many tanks of crushed rock with heat-transfer oil only in tanks where heat is being transferred to the crushed rock or from the crushed rock. At any other time the different tanks would contain hot or cold crushed rock (without oil). This reduces the inventory of expensive heat-transfer oil to what is in the piping and tanks where one is adding or removing heat from the crushed rock. Most tanks at any one time have no oil in them—either hot or cold rock. Round-trip

efficiencies can approach 80%; that is, if a megawatt hour is generated without storage, 0.8 MW hours of electricity is generated from the stored heat. The Korean design proposes that the storage system be built as a large barge (60 m by 450 m) with multiple tanks having a total heat storage capacity of 20 GWh of electricity. The barge, the size of a supertanker, would be delivered to coastal nuclear power sites where it would be floated into a dry dock at the reactor site. Hot-oil heat transfer also allows easy coupling to industrial heat customers.

Germany (Odenthal et al., 2019) is experimentally examining nitrate salts in single tanks filled with crushed rock with lower-density hot salt on top of higher-density cold salt. This is a thermocline heat storage system. The crushed rock is both a heat storage material and helps minimize mixing between hot and cold liquid nitrate salt. The single tank reduces costs relative to the use of separate hot and cold salt tanks.

In third generation systems, where only limited work has been done (Forsberg, 2020), heat is stored in crushed rock in insulated and covered trenches up to 60 m wide, 20 m high and a kilometer long. A leak-tight roof over the trench provides for insulation and allows a controlled atmosphere. For systems coupled to LWRs using oil as a heat transfer medium, every 10 m of crushed rock provides about one GWh of heat storage assuming a 200 °C hot-to-cold temperature swing. Total system capacity could exceed 100 GWh of heat storage. When there is excess energy available, some of the steam from the reactor can be used to heat oil rather than being sent to the turbine-generator to produce electricity. The hot oil is sprayed over sections of crushed rock to heat the rock as it flows down to the oil pan under the crushed rock. The oil is collected and cycled back to the reactor to be reheated. Crushed rock is heated sequentially by section over time (Fig. 3). At times of high electricity demand, cold oil is sprayed on the hot rock, flows through the rock, collected by the oil pan, and used to convert water into steam. A nitrogen gas atmosphere is maintained above the crushed rock to prevent degradation of the heat-transfer oil. The steam is sent to a peaking steam turbine-generator to produce electricity. There is an equivalent parallel system for nitrate salts that operates at higher temperatures approaching 600 °C. The atmospheric composition is controlled to minimize nitrate salt degradation with time.

With the oil and salt systems, appropriate rocks must be chosen to avoid chemical reactions and to ensure appropriate mechanical integrity under temperature cycling conditions. Liquid clean-up systems will be needed to remove rock fines and other impurities that will build up over time. This system with oil or salt has the potential to be the lowest cost system (Forsberg et al., 2020b). Crushed rock is the lowest cost heat storage material available. Flowing the salt or oil over the rock rather than filling all the void spaces in the rock minimizes the inventory of more costly heat transfer fluid. The large size minimizes the surface to volume ratio and thus the cost of insulation and structural materials. Significant development work is required to elevate this system to commercial readiness.

Other researchers are also investigating crushed rock for GWh heat storage systems because it is the lowest-cost heat storage material. Siemens (Kosowatz, 2020) is developing a hot rock heat storage system where air is heated by electric resistance heaters at times of low electricity prices, and the hot air is blown through the crushed rock to heat it to 650 °C. At times of high electricity prices, cold air is blown through the hot rock to produce hot air for a steam boiler.

The U.S. Department of Energy goal for the capital cost of heat storage systems is \$15/kWh of heat. The commercial nitrate salt storage system costs are approaching \$20/kWh. The projected costs for second generation nitrate-salt crushed-rock heat storage systems are near \$10/kWh, whereas predicted capital costs for some of the third generation systems are only a few dollars per kWh (Forsberg, 2020) in sizes to 100 GWh to enable weekend/weekday storage. At present, commercial heat storage system costs per unit of electricity are a factor of three to four less than electricity storage technologies. Advanced heat storage technologies have the potential to be an order of magnitude lower cost than electric storage technologies in the future, reflecting lower cost materials of construction (i.e., crushed rock and thermal salts versus lithium, cobalt, carbon, or steel) and higher operating efficiency.

Cast iron with cladding

Sensible heat can be stored in tanks filled with solid tightly-packed hexagonal assemblies 10–20 m high made of cast iron, with a stainless steel or other cladding chosen for chemical compatibility to match the coolant—sodium, salt, lead or helium. The pumped coolant flows between the solid assemblies. It is compatible with any reactor coolant with the appropriate choice of cladding. The storage system can be located in the primary system or intermediate reactor heat transfer loop. It may be particularly attractive for SFRs with its low-pressure secondary loop because (1) iron is considerably lower cost than sodium and (2) the fire hazard associated with storing large volumes of sodium is eliminated. The geometry is similar to a SFR reactor core that has hexagonal fuel

Fig. 3 Sequential heating crushed rock bed with hot oil.

assemblies; thus, the behavior of such geometries as a function of temperature is well understood. Cast iron is inexpensive, thus the key economic question is a manufacturing question: how far can one drive down the cost of large ingots clad with stainless steel when mass produced? Such storage systems have higher capital costs than crushed rock systems but have very small temperature losses from reactor through heat storage to the power cycle. Such systems are potentially attractive for daily heat storage but not for longer time periods.

There is ongoing work to develop advanced CSP systems that use sodium rather than nitrate salts. Sodium allows higher operating temperatures, has better heat transfer properties and does not thermally decompose if heated. The CSP sodium temperatures would be higher than in SFRs because there are no safety implications if sodium boils. Sodium systems enable the use of alternative power cycles including open-cycle gas turbines with (1) higher-temperature heat and (2) higher-performance lower-pressure-drop sodium-air heat exchangers. There is work necessary to develop gas turbines that would couple to SFRs and is directly applicable to sodium CSP systems (Forsberg, 2020). The potential to couple to lower-cost gas turbine power cycles creates significant incentives to develop such a storage system for sodium CSP plants that would be directly applicable to SFRs.

Geothermal heat storage

In a geothermal heat storage system thermal energy is stored by injecting hot water heated by steam from the reactor into an underground reservoir; energy is discharged by pumping hot pressurized water back to the surface for electricity production in a conventional geothermal plant. Only limited studies have been completed (Lee et al., 2010; Lee, 2011; Forsberg, 2012), but there is a large experience base for the key technologies. Steam and hot water injection is used to recover heavy oil. Many geothermal power plants exist around the world. This heat storage technology has different characteristics than the other heat storage options described, namely:

- *Gigawatt year capacity.* Geothermal storage can provide seasonal energy storage but can only be deployed as a large system because there is no way to insulate rock deep underground. In an ideal system to minimize heat losses, the heated rock zone would be spherical to minimize the surface (heat loss) to volume (heat capacity) ratio. Practical systems have underground geologies that are large rectangles. The minimum heated rock zone to reduce conductive heat losses has dimensions of hundreds of meters. The minimum capacity of heat storage system to avoid excessive heat losses is greater than 0.1 GW·year—far larger than any other heat storage system. The system size can be tens of gigawatt years. The round trip efficiency of these systems is lower than other options, but the incremental capital cost is extremely low.
- *Geology limits.* The right geology is required to implement geothermal storage. The geology must be reasonably permeable to water flow. There is also the requirement that the rock solubility in the fluid be reasonably low to prevent dissolution of the rock and excess dissolved solid contents in the fluid.

Steam power cycle options

There are several heat storage systems that are intrinsically coupled to the power cycle. In a steam accumulator (Forsberg, 2019) there are pressure vessels filled with cold water. At times of low electricity prices, steam is injected into the water, raising its temperature to the boiling point. For a LWR, the pressure would match the peak steam pressure. At times of high electricity prices, valves are opened, the water flashes to steam, and the steam is sent to turbines. Banks of pressure vessels are used to provide steam to turbines at different pressures. Steam accumulators have been used for a century for various applications; thus, the technology is well understood. This experience base includes the building and operating for several decades of a peaking steam accumulator in Berlin that was coupled to a coal plant but was shut down when the coal plant was shut down. At times of low electricity demand, the steam accumulator would be charged to produce peak power when required. Steam accumulators do have one unique property—the response time can be very short with fast increases in power levels. There have been limited recent studies to understand the economics in the context of capital costs and markets.

An additional option is to use cold water for peak power production. On hot days the power output of nuclear reactors decreases as cooling water temperatures increase and steam condenser temperatures increase. At times of low electricity prices, water can be cooled to near its freezing point and stored. At times of high prices, the cold water is used to lower steam condenser temperatures to increase turbine output. Heat storage costs can be very low by storing water in deep ponds where the cold water stays at the bottom of the pools. There are also options to put a floating insulator on top of the water. The system costs are driven by the cost of refrigeration. The economics of this system are strongly dependent upon how many hot days per year and thus the number of storage cycles per year (Forsberg et al., 2019).

Other options

There are several classes of thermochemical systems where heat is stored in chemical bonds. In hydride systems heat is used to decompose a hydride, producing hydrogen that is stored. When the reaction is reversed, the formation of hydride releases heat. In carbonate systems heat is used to decompose a carbonate, such as calcium carbonate, into calcium oxide and carbon dioxide. The carbon dioxide is stored. When the reaction is reversed to form the carbonate, heat is released. Finally, there are a set of chemical reactions that involve forming hydrates where steam is released when the hydrate is heated and heat is generated in the reverse direction. All of these systems are at much earlier stages of development.

Relationship between storing heat, work (electricity) and chemical (hydrogen) energy

The broad classes of energy storage systems are based on thermodynamics: heat, work, and Gibbs free energy. Their fundamental characteristics are reflected in the design of storage systems.

Heat storage couples to thermal generation technologies (e.g., nuclear, fusion, geothermal, fossil fuel with CSS) and, on the product side, with power conversion technologies to produce electricity and with heat users (industry, commercial, etc.). Heat storage is inexpensive because the materials of construction of heat storage systems have very low costs (rock, salt, etc.). Converting heat to work requires power cycles (steam, supercritical carbon dioxide, gas turbines, etc.). It takes time to transfer heat to the power cycle and for power cycle startup; thus, response times are slow—minutes to hours. The response times are faster if the power cycle is operating at part load. There are massive economics of scale that can be leveraged. The characteristics of heat storage suggest that it has the potential become the low-cost primary large-scale storage technology for storage periods from 1 h to 1 week at sizes measured from a few megawatt hours to a hundred gigawatt hours.

Electricity storage technologies couple to electric generating technologies (e.g., wind, solar PV) and the electricity grid. Work is a more valuable form of energy than heat because it takes several units of heat to produce one unit of work. Electricity storage systems (batteries, capacitors, etc.) are more expensive because their construction requires the use of more expensive materials in more refined engineered forms (batteries, flywheels, etc.). Most of these systems have fast response and thus are likely to become the preferred storage technologies if rapid response is required for short periods of time (frequency control, short peak times, etc.).

The two exceptions to these broad characterizations are hydroelectricity and nuclear geothermal heat storage. Each of these technologies is dependent upon geology; hence, their performance and cost are more dependent upon the specific site geology and topography than the technology. Nuclear geothermal systems require a permeable rock formation several hundred meters underground and rock formations with limited rock-water interactions. Hydroelectricity systems require impermeable rock near the dam site to avoid water flow around the dam site and/or dam failure. Topography is only one limitation on siting hydroelectric facilities of any type.

The third class of energy storage technologies is chemical storage, where the primary chemical form is hydrogen (IEA, 2019). There is a large existing demand for hydrogen because of its chemical characteristics. The U.S. consumes 10 million tons of hydrogen per year to produce liquid fuels, chemicals, and fertilizer. Recent studies (Ruth et al., 2020) have examined alternative hydrogen futures with high-end scenarios increasing hydrogen production by a factor of 10 with 17% of total energy production being used for hydrogen production. Hydrogen is a chemical reagent in the production of fertilizer, metals, and liquid fossil fuels where in most cases there is no substitute. It is likely to replace fossil fuels as a chemical reducing agent in the production of steel and other materials, reducing carbon dioxide emissions associated with steel manufacturing by as much as 90% (Millner et al., 2017). Other large future markets include production of high-quality biofuels, use in fuel cells for vehicle transport, and hydrogen combustion as a high-temperature heat source for industry. In each of these three future markets hydrogen is used as an energy source and there are competitive alternatives.

Today hydrogen is primarily produced from fossil fuels. Hydrogen is used on a large scale, moved long distances by pipeline in large volumes and stored at low costs in underground facilities. There are two primary hydrogen production options: reforming and water splitting technologies. Steam methane reforming (SMR) of fossil fuels (where inclusion of CCS reduces the carbon emissions) is the predominant method of hydrogen production today. Hydrogen is a chemically reduced form of methane (CH_4), whereas for water-splitting processes hydrogen is in its oxidized form—water (H_2O). In SMR natural gas and steam are converted to hydrogen and carbon dioxide, taking less energy than electrolytic processes. In a low-carbon world SMR will likely be economic in locations with low natural gas prices and good carbon sequestration sites, partly because the resultant carbon dioxide from the process is concentrated. Water electrolysis for hydrogen production is accomplished via low temperature electrolysis (LTE) of water using electricity, high-temperature electrolysis (HTE) of steam, or thermochemical hydrogen production from water with heat input (see Suppiah, 2021; Boardman, 2021). These processes are less technically mature than SMR. HTE has significant economic advantages (IEA, 2019; Pinsky et al., 2020) because (1) part of the energy input is in the form of steam that costs less than electricity, (2) no expensive catalyst is required and (3) it is more efficient. While one cannot predict technological futures, the expectation is that HTE will likely become the low-cost electrolytic route. There are large incentives to integrate heat storage and hydrogen. At times of low-electricity prices heat from the reactor goes to heat storage and HTE. That heat and electricity from the grid produces hydrogen. This is more efficient than converting excess grid electricity to stored heat and back to electricity where the round-trip efficiency is below 50%.

Hydrogen production facilities are capital intensive, not just due to the production process but also the compressors, pipelines, and associated facilities—all with large economies of scale. Nuclear-driven hydrogen production facilities show technical and economic potential in existing U.S. markets (Frick et al., 2019; Boardman et al., 2019), and U.S. utilities are currently working to demonstrate these technologies at existing LWR power plants.

Conclusions

Historically, fossil fuels provided variable electricity and heat to meet human needs. This was economic because fossil fuels are storable, the capital cost of power conversion equipment is relatively low, and most of the cost was in the fuel. Hence, it is economic to operate fossil power plants and boilers at part load. In a low-carbon economy energy storage is required to match energy production

with energy demand to minimize the energy production costs from high-capital-cost low-operating-cost nuclear, wind and solar. Operating these technologies at part load is expensive.

Nuclear reactors produce heat and thus couple to heat storage technologies. The cost of heat storage today is a factor of three or four less than storage of electricity. The cost of advanced heat storage systems may be an order of magnitude less than electricity storage systems; however, the development of these technologies lag electricity storage technologies. This is because markets for electricity storage have existed for a century, whereas interest in thermal storage is only more recent. The low cost of heat storage has the potential to provide nuclear energy with a large competitive advantage to provide variable heat and electricity.

Finally, very low-cost nuclear heat storage may be the enabling technology for the larger-scale use of wind and solar by storing excess energy at times of low prices to be used as heat and electricity when needed. A nuclear system with heat storage (Fig. 1) has the electrical interconnection to export peak electricity when needed. The same transmission lines, transformers and other equipment enable receiving electricity from the grid at times of low demand. The same peaking power units are used for heat from storage whether it came from the reactor or electricity purchased from the grid. The primary added cost is incremental expansion of the heat storage system—making the system a very low-cost option to beneficially use any excess electricity from wind and solar. The system design is as important as the design of the specific storage technology.

Glossary

Brayton cycle A thermodynamic work cycle named after George Brayton that describes the workings a gas compression, gas heating and gas expansion turbine a gas cooling source, and gas compressor. Paired to a heat source. A once-through air Brayton cycle draws and discharges air from the ambient atmosphere. A closed Brayton cycle incorporated a low-temperature heat rejection source.

Exergy The maximum theoretical useful heat and work (pressure-volume, shaft, or electrical) obtainable as the system is brought into complete thermodynamic equilibrium with the thermodynamic environment while the system reacts with this environment only.

High temperature gas cooled reactor A nuclear reactor with a fuel core that is cooled by a gas, such as helium, nitrogen, or carbon dioxide (HGTR).

Light water nuclear reactor Nuclear reactor cooled by normal water (H₂O); either a pressurized water reactor (PWR) with steam generators that typically produces steam up to 330 °C and 17.4 MPa or a boiler water reactor (BWR) that typically produces steam up to 290 °C at 7.6 MPa.

Microreactor A nuclear reactor with a thermal energy output of ranging from one to 20 MW (MW) electrical energy generation.

Molten salt reactor A nuclear reactors with a fuel core that is cooled with a molten salt, such as eutectic mixtures of fluoride/lithium/beryllium (e.g., FLiBe) or sodium/potassium nitrate (e.g., NaNO₃-KNO₃) or potassium/fluoride/zirconium (e.g., KF-ZrF₄).

Next generation nuclear plant A concept for a project to provide nuclear energy to industrial processes; based on the high temperature gas-cooled reactor used for Next Generation Nuclear Plant (NGNP) concepts.

Small modular nuclear reactors A nuclear reactor with a thermal energy output of ranging from 20 to 300 MW (MW) electrical energy generation. Modules may be grouped to form a complex of reactors rivaling the output of traditional large-scale nuclear reactors (MSR).

Subcritical steam Steam at conditions below the critical point of 374 °C and 22.10 MPa.

Supercritical steam Steam at conditions above the critical point of 374 °C and 22.10 MPa.

Ultra-supercritical steam Steam at conditions which are typically greater than 600 °C (and ranging up to 760 °C) and in excess of 24 bar (and ranging up to 34 bar).

Introduction

The Section Introduction discusses opportunities and gaps for application of nuclear produced thermal energy for the process industries. The most common methods of heat deposition in the process industry are performed with fired heaters that provide hot exhaust for gas-to-gas and gas-to-liquid heating, chemical reactor vessel jackets, steam reforming processes, and high temperature processes such as glass, cement, and steel making processes. It is estimated that about 70% of the energy supplied to the process industries is derived by combustion of fuels, including process tail gasses that are conveniently burned to raise heat while avoiding pollutant emissions. It is therefore imperative that strategy intent on achieving deep decarbonization of industry look for a substitute for fossil fuel combustion. Moreover, it is important to note that unlike the transportation sector and electrical grid, energy use by

industry often involves direct conversion of primary energy sources to thermal and electrical energy at the point of consumption. The heterogeneity and variations in scale of industry and the complexity of modern industrial firms' global supply chains are among the sector's unique challenges to minimizing its greenhouse gas (GHG) emissions. Because nuclear energy is essentially GHG-emissions free, concentrated, high quality, and wholly dispatchable, it is a strong candidate for providing process heat for the chemical industries.

This section necessarily begins with a review of best fit industries for initial application of nuclear-supported process heating. McMillan et al. (2016) composed the most complete review to date on process heating that can be supported by solar, geothermal, and nuclear energy sources. The diversity of processes within the industry represents many potential applications for nuclear technologies. Many chemical processes have heat needs within the ranges generated by reactor designs.

Application of nuclear energy to industry is motivated by the same drivers as electrification of industrial manufacturing: reducing overall emissions from the industrial sector. However, the greatest thermodynamic efficiencies are ultimately attained by direct application of the thermal energy produced by nuclear reactors. This is borne out by understanding and applying a thermoeconomic analysis. Application of the 1st and 2nd Laws of classical thermodynamics leads to an assessment of the disposition of the exergy input into the system. Exergy is the maximum theoretical useful heat and work (pressure-volume, shaft, or electrical) obtainable as the system is brought into complete thermodynamic equilibrium with the thermodynamic environment while the system reacts with this environment only (Tatsaronis, 1993). This necessitates a systematic analysis of both the work-producing (e.g., electrical power) and work-adsorbing processes (e.g., a gas liquefaction column or a chemical product reactor) unit operations.

Industrial heat requirements

Fig. 1 shows the breakdown of emissions and the concentration and level of heat use by major industrial sectors. While the potash/soda ash/borate mining industry has relatively low total emissions and relatively few facilities over the reporting threshold, each plant consumes a large amount of thermal energy. Petroleum refineries account for the most emissions among considered industries, with many refineries in the U.S. consuming moderate levels of thermal energy.

Approximately one-half of the heat used by industry is provided by package boilers to raise steam, which is the predominate medium of heat transport and heat transfer. Space heating accounts for about 20% of the total fuel usage, most of which is for boilers in houses.

The majority of steam duties simply require subcritical steam. Some applications may utilize supercritical steam, but it is rare for any process to use ultra-supercritical steam, except in power generation, given the corrosivity of high temperature steam which necessitates expensive alloys. For very high temperature processes, either direct or indirect heating with combustion gasses is the most common practice. However, with the advent of advanced, high temperature reactors, it is desirable to substitute steam duties with non-corrosive hot gasses. Inert gasses such as He and CO₂, or even heated air, are some choices.

The common feature of all process industries is that they aim to convert raw materials into a new form by means of chemical and physical changes. Some of these "processes" are listed in Table 1. Most require external heat, some in very large quantities.

Fig. 1 Size and emissions of selected industries in the United States.

Table 1 Process industry examples of processes using heat.

Process industry	Examples of processes using heat
Petroleum refining	Feedstock heating, distillation, hydrocarbon cracking, hydrocarbon reforming (i.e., steam-methane reforming)
Chemicals (includes ammonia, fertilizers, pharmaceuticals, alcohols, detergents, resins, polymers, textiles, paints/pigments/dyes)	Endothermic chemical reactions, hydrogenation, pyrolysis, distillation, purification, evaporation, crystallization, polymerization, drying, prilling
Metals Manufacture (includes iron, steel, copper, and other non-ferrous materials)	Smelting of ores, refining, alloying, melting, casting, forging, rolling, annealing, soaking and heat treatment, sintering
Nonmetallic Minerals and Acids (includes phosphorous, soda ash or caustic, sulfurous, chlorine, alkalis/alkaline)	Slurry concentration and drying
Refractories (includes bricks, pottery, glass, cement, and other refractory materials)	Firing, kilning, drying, calcining, melting, forming (e.g., plate glass), annealing
Wood Product (includes lumber, paper, and paperboard)	Kiln drying, wood pulping and liquefaction, rolling, drying, coating, and forming
Food and Drink (includes dairy products, brewing, farinaceous products, meat and vegetables, soft drinks, and tobacco)	Milling, blending, forming as liquids, powders, or composite solids, purification, sterilization, pasteurization, fermentation, refrigeration
Sugars and artificial sweeteners	Glucose-to-fructose conversion, artificial sweeteners
Industrial gasses	Temperature-swing adsorption

Nuclear reactors for process heating

Nuclear heat is well-matched to process heating, and in some cases vaporizing chemical feedstock entering a reactor process. Nuclear heat can be directly substituted for steam that is used indirectly to dry, concentrate, or distill most aqueous solutions and to fractionate petroleum distillates. In some cases, nuclear heat can be used to break low-order chemical bonds such as biomass ligands or coal moieties. In summary, approximately 75% of all industrial heat duties require less than 700 °C, with about 50% of the duties being less than 300 °C.

Combining original graphs first presented by McMillan et al. (2016) and Massachusetts Institute of Technology (MIT, 2018), Fig. 2 visualizes the temperature ranges of process heat required in selected industries, while the Introduction tabulates and compares to the output temperature limits of different nuclear reactor designs. As the figure indicates, advanced nuclear reactors

(ARs) produce higher-quality heat than light-water reactors (LWRs), and therefore have a greater potential to replace existing industrial heat sources. Combined with an efficient, high-temperature heat transport system, such as solar industrial process heat systems used with solar concentrators, sodium fast reactors (SFRs), molten-salt reactors (MSRs), and high temperature gas-cooled reactors (HTGRs) are expected to be capable of supplying process heat for most processes in these industries without the need for topping heat. Where necessary, low-carbon heat augmentation can be supplied electrically or with chemical heat pumps (Bragg-Sitton et al., 2020). Also, use of advanced nuclear reactors in industries or plants with processes requiring lower-quality heat provide the opportunity for bottoming processes, such as electricity production. In light of these findings, and based on temperature compatibility alone, none of the industries in Fig. 2 should be excluded from consideration for thermally coupled nuclear energy systems.

Naturally, a reactor's thermal output capacity must exceed the thermal energy consumption requirements of the industrial plant or plants that it serves. Fig. 3 shows the distribution of plant thermal energy consumption in four of the industries of interest. Plant size aligns well with the size of advanced reactors, which are expected to range from 1 to 20 MW_e for microreactors, 20 to 300 MW_e for small modular nuclear reactors (SMNRs), and from 300 to 1000 MW_e and higher for full-size reactors. A breakdown of advanced reactors under development is given in a fact sheet by the United States Department of Energy (2020).

Chemical process considerations (subheading)

The main challenge for nuclear reactors is replacing fired-heaters that provide on-demand heating of chemical processes. The chemical process reactors, in which chemicals are made in industry, vary in size from a few liters to several cubic meters and hold, at any one time, well over 100 t of materials. The design of the chemical reactor is determined by many factors, but of particular importance are the thermodynamics and kinetics of the chemical reactions being carried out.

In processes such as cement kilns, float glass making, and metals annealing, hydrocarbon-flames transfer heat by radiation to heat exchanger surfaces with the reactor vessel or process. Cement kilns and metals decarbonization require very high temperatures that cannot be indirectly transferred to the solid. Hydrogen can be burned to provide very high temperature gasses; however, hydrogen flames are virtually invisible and produce very little radiant heat to support indirect heating of a material.

The basic concepts for chemical process heating, evaporation, and reaction heating are illustrated in Fig. 4. When evaluating the use of nuclear heat sources for the chemical industry, it is important to understand the chemical processes and the equipment used for feed heat-up, phase-changes, and reaction enthalpy requirements. Heat recuperation must be optimized in a manner that optimizes the use of the nuclear heat source. Finally, heat augmentation may be applied, but only when the net effect uses the energy contributed by the nuclear heat source (for example, see Fig. 4F).

Fig. 4 Nuclear heat transport to chemical process heaters and chemical reactors.

Fluid mechanics considerations (subheading)

A number of integration issues must be considered when applying process heat applications to nuclear reactors. These considerations include:

- Reactor outlet temperature
- Reactor inlet temperature
- Fluid composition
- Pressure within coolant, heat transfer loop, and process heat application
- Tritium migration

Low temperature reactors—typically LWRs—can provide process heat to most industrial applications. Steam heating can be accomplished with topping heat from fossil fuels and/or electric resistance heating for higher temperature process heat applications. Conversely, high temperature heat produced by a high-temperature gas-cooled reactor (HTGR) or molten-salt reactor (MSR) may exceed the temperature limits of a given reaction process. In this case, a top-cycle use can be advantage, such a power generation unit. This is essentially the concept of a combined heat and power systems that converts supercritical pressure steam into power while dropping the pressure and temperature of the steam to the desired industry service quality. Similarly, a bottoming cycle may be necessary to lower the temperature of the heat transport media before its return to the nuclear heating loop.

In the case of the HTGR, the temperature difference of the gas temperature across the core optimally needs to be 350–450 °C. For most MSR concepts, the temperature difference is generally 50–150 °C, given the higher heat capacity of the salt versus a gas. In summary, the temperature of the thermal hydraulic heat delivery system must be carefully engineered. The choice of nuclear reactor depends on the industry heat application.

The melting temperature of liquid coolants, such as molten salts and sodium, and the heat transport system must be designed and operated to avoid freezing the salt. Depending on surrounding temperature, it may be necessary to insulate the pipes, pumps, and control valves of the delivery systems or to provide some form of electrical or jacket heating to re-liquify the frozen salt. Steam, carbon dioxide, and helium do not have such issues, although steam condensate traps and blow-out lines are needed at latitudes and altitudes where temperature may drop below the freezing point. For this reason, synthetic oils have become a preferred heat delivery media.

Heat transfer distance and the working fluid can both be limiting factors when considering industrial process heat input requirements. In the case of an application similar to the following artist's rendition (Fig. 5) created by the Next Generation Plant Alliance

Fig. 5 Artist rendering of the High Temperature Gas-Cooled Reactor to industrial plants. Source: Next Generation Nuclear Plant Alliance. (Nelson L, Gandrik A, McKellar M, Patterson M, Robertson E, Wood R and Maio V (2011) Integration of high temperature gas-cooled reactors into industrial process applications. *Idaho National Laboratory External Report, INL/EXT-09-16942 rev.3, September 2011.*)

(Nelson et al., 2011), coupling between the nuclear reactor and one or more industrial processes may involve a heat transport distance less than 1 km. As this distance expands, the choice of heat transport media and thermal energy circulation loop become more important. The tradeoff between liquid pumping and gas compression costs may alone determine the choice of heat transfer media.

Long heat transport distances (subheading)

Engineering considerations for heat-transfer distance, such as capacity matching and working fluid temperature, are straight forward, but not necessarily easy. Steam/water and molten salts perform better than gasses for relatively long heat-transfer distances (up to 20 km), primarily because gasses such as helium require extremely high pumping power (McKellar, 2011). The high pumping power makes long-distance hot-gas heat transport applications impractical (Yoon and Sabharwall, 2014; McKellar, 2011).

Fig. 6A and B compares the transport of molten KFZrF_4 to helium using a circulation loop of a comparable size. For this comparison, the pipe is considered to be buried, although this may not be practical when considering thermal-expansion design requirements. The molten salt, having the highest volumetric heat capacity and lowest pumping energy, is capable of transporting 54.4 TJ/day or 629 MW_t (at a coefficient of performance of 4670 TJ/day- MW_e) versus 16.3 TJ/day or 188 MW_t (at a coefficient of performance of 4.85 TJ/day- MW_e) using helium in the same sized piping system. The coefficient of performance is the heat divided by the pumping or compression power used to transport the heat. In a practical engineering design, pipe material and corrosion, as well as pump versus compressor costs, are important considerations.

Process heat applications generally require a secondary heat transfer loop to isolate the primary core cooling loop from the process heat application. One purpose of this secondary loop is to reduce the migration of tritium from the reactor core to the process product. Additional heat transfer loops may be added to reduce tritium migration, but each loop degrades the exergy of the process heat temperature.

Temperature boosting (subheading)

Temperature boosting through heat pumping is one approach to use energy conversion processes to create high temperature heat from the relatively low temperature heat produced by LWRs. There are a variety of possibilities for these conversions; some of which are illustrated in Fig. 7A–E. Thermodynamic principles require a net input of work to raise the temperature of heat in this manner, with more work needed as the final temperature increases. If an LWR provides the work input, the net effect is to convert a given amount of its 300 °C heat into a somewhat smaller amount of high temperature heat. However, this high temperature heat comes from a CO_2 -free non-combustion source, providing environmental benefit relative to most current industrial practices. Table 2 compares other factors specific to each of these cycles. A variety of chemical looping possibilities have been developed. An exergoeconomic analysis is required to justify any application of these concepts.

Example: Use of nuclear heat for methanol production

Methanol is one of the predominant commodity chemicals in the United States and around the world. It is a feedstock to produce chemicals, such as acetic acid and formaldehyde, which in turn are used in products such as adhesives, foams, plywood subfloors, solvents, and windshield washer fluid. In recent years, the use of methanol in the production of olefins, or methanol-to-olefins, has grown rapidly (Alvarado, 2016). Methanol can also be used on its own as a vehicle fuel or blended directly into gasoline to produce a high-octane, efficient fuel with lower emissions than conventional gasoline.

There are at least two opportunities to replace natural gas combustion in methanol production: one is the heat needed for the primary reformer, and the second is the heat required for methanol purification. The former case is illustrated Fig. 8. In conventional steam reforming, methane is reformed in tubes within a furnace. Heat is provided by firing natural gas. Heat transfer from the flame to the tubes is primarily via thermal radiation.

When heat is available above 700 °C (i.e., high temperature molten-salt or gas-cooled reactors), it is possible to integrate nuclear heat directly into the natural gas reforming process, thus displacing combustion of natural gas as the primary source of reforming heat. A brief discussion of heat integration for the various scenarios is presented below.

Fig. 9 shows a simple block flow diagram indicating heat delivery to the primary reformer in a natural gas reforming plant (Wood and McKellar, 2013). In this example, the primary coolant for a fluoride/lithium/beryllium (FLiBe) high temperature reactor (FHR) is used to heat helium, which is then pumped into the primary natural gas reforming heating box. The hot helium replaces the hot gas produced by natural gas combustion, which in some reforming plants consumes as much as 30% of the natural gas input to the plant. The helium loop also provides separation of the primary reactor coolant from the chemical plant.

Bragg-Sitton et al. (2013) evaluated the technical and economic feasibility of producing methanol using a hybrid system in which the FLiBe salt is circulated in two parallel loops (Fig. 10): (1) a primary loop that exchanges heat with a helium heat transfer loop to deliver heat to a methanol plant in the manner described above, and (2) a secondary high temperature heat transfer loop

Fig. 6 Operating conditions and performance of high temperature reactor heat transfer loops (McMillan et al., 2016). (A) 2-km helium circulation loop, where the dimensions for pipe section 1 are tabulated, and (B) 2-km KFZrF₄ molten-salt circulation loop, where the dimensions for pipe section 1 are tabulated.

Fig. 7 Temperature boosting heat pump concepts. (A) Conventional power production, Use of electric power to generate heat, (B) fossil-fired topping cycle with nuclear heat, (C) split-duty heat pump, (D) looping chemical reaction.

Table 2 Comparison of energy conversion cycles for making high temperature heat.

Process	Delivery temp. range	Heat delivery efficiency	Advantages	Disadvantages	Comment
Rankine cycle	Makes power	32–34% as power	Well established technology	Makes power, not heat Fairly low efficiency	Reference process
Electric-based heating	To melting point of materials, 1500 °C	33% to power, 100% power to heat	Well established technologies Easy to integrate into applications	Fairly low efficiency No particular synergy with nuclear generation	Isothermal heat delivery
Fossil-fired topping	To melting point of materials, 1500 °C	~85% for furnace	Well established technology	Half or more of heat input comes from the furnace Associated CO ₂ emissions	Energy delivered as sensible heat over a temperature range
Split duty heat pump	ca. 200 °C increase per stage	~60% per stage, rest is reject heat	All energy comes from the nuclear reactor Adaptable for cogeneration Only a small amount of equipment sees high temperatures	High temperature compressors are not standard items (but turbines are)	Explore working fluids besides steam
Chemical reaction for heat delivery	ca. 800 °C, perhaps to 1000 °C	Estimated 60–70%	Can support long distance heat delivery by piping cold gas Storage of energy (as syngas mixture) is possible Could integrate with a HTGR	Requires intermediate temperature heat input for reforming (could potentially integrate with a heat pump)	Explore other endothermic chemistry, such as water splitting Heat can be delivered roughly isothermally

Fig. 8 Energy use in synthetic gasoline production for use in methanol synthesis.

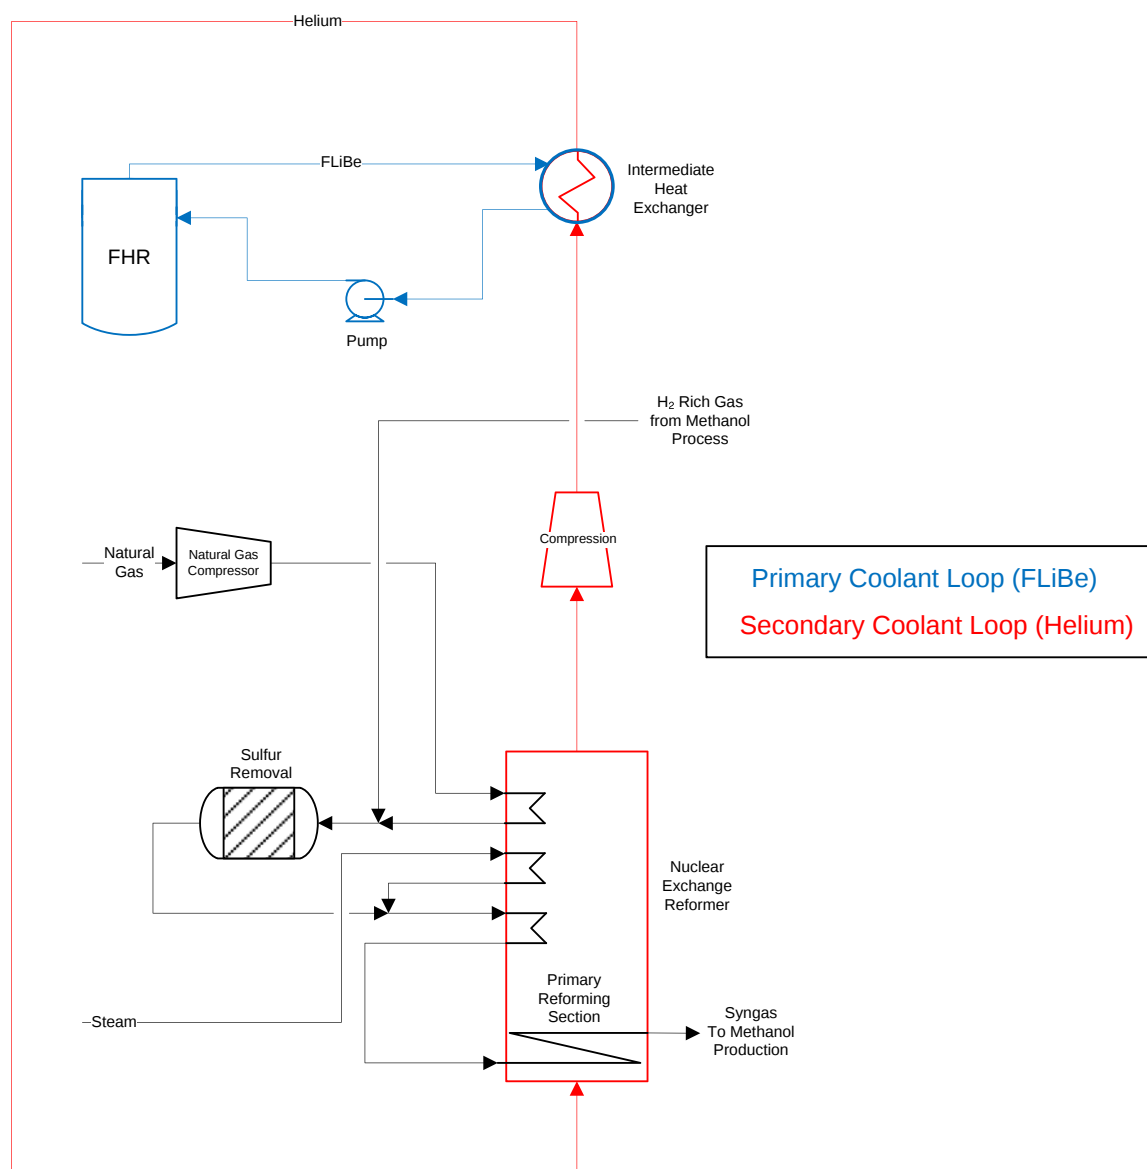

Fig. 9 Steam methane reforming with a fluoride-salt high temperature reactor (FHR).

Fig. 10 Advanced hybrid FHR methanol configuration.

fluid that uses molten KF-ZrF_4 salt to transfer heat to a supercritical CO_2 Brayton Cycle power generation plant. The pressure of the helium loop was set at 9 MPa.

The methanol process generates some excess steam that is fed to a small Rankine cycle. The amount of power generated from this cycle, however, is insufficient to meet the entire electrical duty of the plant. The Brayton cycle therefore supplies power to the methanol plant to avoid the need for the methanol plant to import power from the grid. Excess power can be sent to the grid—an action that can be desired to support grid demand.

A discussion of the economics for the hybrid methanol and electrical power case is presented by Bragg-Sitton et al. (2013). For this case study, a dynamic model was developed to evaluate the profitability (measured in terms of the net present value of the project) as a function of variable energy apportionment between the power cycle and the chemical plant. The study developed a physics-based transient process model to simulate dynamic ramping of the natural gas reforming and power generation blocks in accordance with grid demands tied to wind power variation and grid supply demands. This type of hybrid system results in underutilization of the capital assets while optimizing profit by responding to the highest value market. For this case study, a positive profitability of this example hybrid system was achieved when wind penetration exceeds 20% of total system capacity. This was attributed to the high value of electricity when reserve capacity is required.

Additionally, at approximately this level of variable power generation capacity, traditionally baseload plants begin to be affected and are required to flex their operations. The benefits of an integrated plant, and similar hybrid systems, depends on the local grid markets, the chemical commodities markets, and the stochastics of variable power generation sources.

Conclusions

This section highlights the opportunity to use nuclear heat for a wide spectrum of industrial manufacturing processes. This could arguably reduce industry GHG emissions by 90% when eliminating combustion in steam boilers, combined heat and power systems, fired-heater, and high temperature processes. The application of nuclear heat may be as simple as supplementing or

replacing the steam duties of a plant to direct heat transfer to a chemical reaction process vessel. The cost of nuclear depends on many factors, but the impetus to reduce climate altering gasses like CO₂ provides motivation to the nuclear heat sources. There remains a significant amount of research to understand the optimum choice of nuclear reactor to use and the separation between tightly coupled systems. However, the studies that are being completed in this area, including the limited examples shown in the Chapter, are promising. Dynamic operation of integrated energy systems is especially of high interest because these systems can help firm the grid when the penetration of variable generation sources like wind and solar energy begins to affect traditional baseload plant operations.

Glossary

Conventional power production plants Electricity producing plants that include hydroelectric dams and all thermal plants, e.g. coal, fuel, gas and nuclear power plants.

EAF Electric Arc Furnace, a furnace in which metal is melted thanks to an electric arc.

EAS Electric Arc Steelmaking, the process of recycling steel from scrap steel in an EAF.

Electrolytic process Industrial process that uses, at least at one step, an electrolysis.

Flexibility The capacity, for a power plant or an electric load, to change its power production or consumption.

FT process Fischer-Tropsch process, a process that produces liquid hydrocarbons from syngas, which is a mixture of carbon monoxide and dihydrogen.

(Electricity) Grid stabilization The balancing of power flows in an electricity grid so that no line is congested and global electricity production equals global electricity consumption.

Load shedding The reduction of the electricity consumption of a load to help grid stabilization.

(Variable) Renewable Generation Power generation coming from variable and renewable sources such as wind and solar power productions.

RO Reverse Osmosis, most common process to produce pure water from seawater or brackish water.

Introduction

Industrial processes tend to be used more and more by electricity grid regulators for the wide range of services they can provide. In fact, grid stabilization is a synonym for regulating power flows in a possibly multi-state electricity grid, and industries, because of their significant electricity consumptions, could play a major role in power flows. In particular, industries can participate in balancing consumption and production of electricity at all times, or in relieving grid congestions when the maximum capacity of an electricity line is reached, simply via smart management of their electricity consumption.

Those services are especially required since some hazards affect grid stabilization on a daily basis, like unexpected technical constraints on power production units, or more commonly forecasting errors, whether they concern the consumption of electricity, or the production coming from renewable sources (e.g., wind and solar power production mostly). Those uncertainties have been historically compensated by automatic and manual modifications of the setpoint of conventional power production units, including nuclear power production units. However, the growing share of renewable generation in the power production mix not only increases the amplitude of the hazards due to forecasting errors, but it also decreases the amount of flexibility offered by conventional power production units. Besides, new uses of electricity, such as electric vehicles or load shedding, affect the electricity consumption forecasts: it is still unclear if these new uses will make consumption more or less predictable.

As a consequence, electricity consumption will have to provide the flexibility that is being replaced by renewable generation. In the USA, total industry energy consumption represents 10,700 TWh in 2018, which is 36% of the world industrial energy consumption of 30,000 TWh (IEA, 2019a). Electricity consumption represents 29% of this number in the USA, which is high, even though this share has been slowly decreasing since 2008, as can be seen in Fig. 1.

Fig. 1 Electricity share in energy consumption in the USA per sector. Data from IEA (2019a) *Data & Statistics—IEA*. [online] Available at: <https://www.iea.org/data-and-statistics> [Accessed 11 Dec. 2019].

Fig. 1 also highlights the fact that the electricity share in residential and commercial consumption is higher than in industrial consumption, for a similar amount of total energy consumption. However, residential and commercial consumptions are distributed on many sites (each individual home or shop being a site) and therefore constitutes a far less manageable load, with a less predictable impact on power flows. Managing electricity consumption is therefore much more economically and technically efficient if it is installed in an energy-intensive factory rather than in a common house. Additionally, it is regarded as more socially acceptable to control the electrical load of an industrial consumer than to control the electricity consumption of common citizens. In the first case, it affects the planning and the design of an industrial process whereas in the second case it may directly affect the comfort of citizens in their homes. Finally, the way industries are managed makes them more sensitive to economic incentives, and if electricity markets and regulations make investing in control devices profitable, industries are likely to adapt faster to those changes and therefore provide the corresponding services.

On the other hand, industrial processes are also subject to more technical constraints than residential and commercial consumers. Unplanned load shedding could result in loss of a full batch of goods for some industries, which can cost up to several million dollars for some products. As a consequence, and it is the object of this article, each industrial process needs to be analyzed to determine if its electricity consumption can be adapted according to the needs of the electrical grid, if it needs to be redesigned, or, finally, if it is simply not suitable for providing such services.

The answer may depend on several factors, in particular how fast the process' electricity consumption can be modified, and how long this modification can last. If no industrial process can provide services as fast as electrical inertia for grid stabilization, as it would require spinning machines connected directly to the grid and operating always at a multiple of 60 Hz, some may be able to, to some extent, adapt their consumption in a few seconds or a few minutes. For time scales shorter than 15 min, it is often considered that the regulation must be automatic and must be performed through a control device directly connected to the grid regulator's system. For time scales longer than 15 min, manual actions can be taken in coordination with the grid regulator, as long as it is technically feasible to manually change the consumption setpoint. For some processes, this last feature is not even necessary: smartly planning when to start or stop the process is already a form of load management. Other dimensions to the answer can also be important, such as the amplitude of the modification of the consumption, its duration, previous activations, etc.

The answer can also depend on economic incentives. The services that can be provided by a given industrial process are sometimes limited by the cost of the required investment. Besides, in some cases where the load has to be shed during long periods of time, or involving a significant amount of energy, the yield of a process, or the daily output of a factory, can be significantly decreased due to electricity grid needs, which means that industrial load management may also have variable costs.

Desalination

Industrial load management can simply be achieved if industries offer some kind of electricity storage. Electricity does not have to be stored directly as in battery storage, but for example in the form of the output of an industrial process. So far, the best kind of grid level electricity storage is performed with pumped-storage hydroelectricity (PSH) power plants, by transferring water between two reservoirs at different altitudes, upstream for downward needs, downstream for upward needs. An analogy can be made with desalination processes: seawater coming from the lower reservoir, and pure water from the upper. The desalination process consumes

electricity and/or thermal energy to turn seawater into pure water, which is equivalent to using electricity to pump water from a lower to an upper reservoir. The opposite effect, if theoretically possible, is less relevant to analyze since pure water is considered to be more needed than grid stabilization services. However, reducing the flow of pure water production compared to what was originally planned can be considered as an additional flow of pure water being turned into seawater while producing electricity. Desalination plants can, therefore, provide a form of electricity storage.

Besides those theoretical arguments, the potential of desalination industries for grid stabilization is huge. According to the International Desalination Association (Idadesal, 2019), there are more than 21,000 desalination plants worldwide, located in more than 150 countries. This corresponds to a total capacity of desalination of 142 Mm³/day, which more than 300 million people rely on for their daily needs. This number is very likely to increase (Jones et al., 2019) as 40% of the global population faces severe water scarcity conditions: this share could even increase to 60% by 2025. This trend is confirmed by the evolution of the global capacity of desalination plants which increased by more than 30% between 2010 and 2020 (Jones et al., 2019).

In terms of energy, the global energy consumption of desalination plants per year is around 350 TWh (Desware.net, 2019; Dach, 2008; Singh, 2015), including 200 TWh of electricity consumption, which is about the total electricity consumption of Spain, and 1% of the world electricity consumption.

However, desalination is not one industrial process, it is achieved through different methods, whose distribution can be seen in Fig. 2 (Jones et al., 2019).

The most common industrial processes to perform water desalination are Reverse Osmosis (RO - 69%), Multi-Stage Flash Distillation (MSF - 18%), Multi-Effect Distillation (MED - 7%), Nanofiltration (NF - 3%) and Electrodialysis (ED - 2%). If, in terms of global installed capacity, all processes are getting more and more widely used, only the share of RO has been increasing since 2000, where it was a bit less than 50% (Jones et al., 2019). This success of RO for water desalination can be explained by the small amount of energy it requires, only 3–5.5 kWh/m³, which is much lower than MSF 13.5–25.5 kWh/m³ (Desware.net, 2019), as well as for the numerous varieties of water it can purify. For example, although NF consumes less than half the electricity of RO, it does not remove all impurities from water. As a consequence, RO global yearly electricity consumption represents 65% of global desalination electricity consumption, which is 130 TWh. This paragraph will therefore focus on RO.

Before analyzing how it could be used for grid stabilization, a good understanding of the process is necessary. RO properly speaking needs a very pure brine input. Consequently, several stages of pre-filtrations are required. This is due to the very sensitive membrane that the process uses: many impurities have the potential to damage it. The problem of filtration is that the smaller the removed particulates are, the more sensitive the membrane used to filtrate them is. The process must therefore be progressive. Different types of filtration are available depending on the composition of the water. Once appropriately filtered, seawater is ready for RO. The process uses two water tanks separated by a special membrane; one contains seawater and the other relatively pure water. The membrane is the core of the process, the progress made in its design explains why this process has become so widely spread. Its function is to allow almost only water go through it. Usually, because of the difference of chemical potentials between the two liquids due to the differences in ionic concentrations, pure water tends to go to the seawater tank to dilute it and therefore equilibrate the potentials. This phenomenon results in a pressure against the membrane called the osmotic pressure. Between seawater and pure water, it is around 27 bar. An RO plant increases the pressure on the seawater side until the flow reverses, which occurs at a pressure above 27 bar (Lachish, 2002). In fact, pressure is usually around 40–82 bar in the seawater tank for matters of kinetics and percentage of recovery. Usually, up to 50% of the water is extracted from seawater with this method. Afterwards, a post-treatment is necessary because in some cases, water obtained by RO lacks essential minerals. Fig. 3 sums up the whole process.

The potential of RO for grid stabilization is huge, not only because it represents a growing and significant share of the electricity consumed worldwide, but also because its process can easily be adapted for load management.

On large time scales, storing water is indeed extremely easy, so, if the desalination system does not need to be used at 100% capacity at all times, planning when to desalinate water could significantly help the electrical grid. This should neither constitute

Fig. 2 Share of main desalination processes in the world. Data from Jones E, Qadir M, van Vliet M, Smakhtin V, and Kang S (2019) The state of desalination and brine production: A global outlook. *Science of the Total Environment*, 657: 1343–1356.

Fig. 3 Diagram of the reverse osmosis process to turn seawater into drinkable water.

an economic loss insofar as the consumption of water would not change in total, nor would the cost of seawater. The only drawback is that this service may require desalination plants to have excess capacity, which is globally true at present (Idadesal, 2019). Another lower cost option could be to only schedule maintenance according to electricity grid needs.

On shorter time scales, and therefore for lower amount of electricity and water involved, other services can be provided by desalination plants. In fact, the major source of electricity consumption in the RO process comes from the high-pressure pumps for seawater. The pressure they impose is usually between 40 and 82 bars for kinetics and percentage of water recovery, but as long as the pressure remains above 27 bar, pure water would not counter-flow from the pure water tank to the seawater tank. This means that, if needed, the pressure produced by the pumps, and therefore their electricity consumption, can be lowered, resulting only in a lower amount of purified water per hour, partly compensated by a slower tiring of the very fragile membranes. Symmetrically, increasing the pressure above the nominal level of the desalination plant, and therefore consuming more electricity, may be more difficult and could damage the membrane unless an appropriate design is chosen for that purpose. Moreover, there does not seem to be any limit to the duration of the modification of the pressure setpoint.

Alumina reduction

World alumina production is 130,433 Mt. in 2018, of which about 53% is produced in China (World-aluminium.org, 2019). Alumina mostly comes from bauxite ore and is obtained through the Bayer refining process. About half of this alumina is then smelted into different grades of pure aluminum through the Hall-Heroult process, which corresponds to 64,336 Mt. of global aluminum production, 55% being produced in China. Aluminum production from alumina is a very energy intensive process since it consumes about 14–15 MWh of electricity per ton of aluminum. The global electricity consumed by aluminum smelting can therefore be estimated around 867 TWh, which is almost 4% of the world electricity consumption, or a quarter of the electricity consumed in the USA.

The Hall-Heroult process is an electrolytic reaction which produces carbon dioxide and aluminum from alumina and carbon through the following reactions:

These reactions take place in a heat-insulated rectangular steel shell with a carbon lining inside, as shown in Fig. 4. The cathode is a conductor going through the shell inside the carbon lining which protects it from the heat but conducts electricity. The anode is covered in carbon and immersed in an electrolyte bath, contained inside the shell. The anode is composed of Na_3AlF_6 , and additives such as AlF_3 and CaF_2 (Li_2CO_3 and MgF_2 are also used), which are used to control the operating temperature, solubilities, activities of ionic species, conductivity, viscosity, interfacial voltage bath density, vapor pressure, hardness of the crust, etc., as well as to increase current efficiency (Starke et al., 2009). AlF_3 is the most common additive. It lowers the operating temperature, the solubility of reduced aluminum, surface voltage, viscosity and density. However, it also decreases alumina solubility and electrical conductivity.

Alumina is fed and dissolved inside the tank through point feeders (its concentration must be kept around 2–8 wt%) to enable the best distribution of alumina in the bath. Alumina is also used to cover the carbon anodes and the frozen bath surface to reinforce

Fig. 4 Diagram of an electrolytic cell used for aluminum production and its shell. Reproduced from Bangs C (2011) *Rolling Out Aluminium to Meet IPCC 2050 - A Dynamic MFA Approach for Greenhouse Gas Emission Projections for the Aluminium Industry*. doi: 10.13140/RG.2.2.19000.75527.

thermal insulation and reduce air burning of the anode. Despite this very accurate feeding, the bath is polarized (gradient of concentration), which increases its resistance.

During the reaction, the carbon anode is slowly consumed (0.45 kg/kg of aluminum produced), creating bubbles (mostly CO_2 , but also CO or even C_2F_6 and CF_4 due to anode effects [local shortage of alumina which can create overvoltage up to 40 V]). Changing the anode when completely consumed is the first reason to stop the plant. The distance between the anode and the aluminum pad being created at the cathode has to be changed permanently given the wearing of the anode and the size of the aluminum pad. This distance is usually 4–5 cm; it is a compromise between reducing the resistance of the bath, keeping the aluminum pad and the anode apart, enabling bubbles to escape and allowing alumina ionic species to easily reach the charged surfaces.

The main restriction to load management in aluminum plants is that the temperature inside the tank must be kept within close values, the heat losses being compensated by Joule losses inside the shell. However, using thermal inertia and the huge quantity of heat stored in the electrolyte bath enables small variations of the electricity consumption of the plant. In fact, the temperature inside the tank must be kept between 950 and 980 °C (Choate and Green, 2003), whereas Na_3AlF_6 usual fusion temperature is 1011 °C, due to the additives in the bath that lower its fusion temperature. As a consequence, there is a wide range of operational temperatures that can be explored, using more or less additives.

Operating at high temperature presents the advantage of opening a wider range of power consumption as well as alumina concentrations, but it is very energy-intensive and may destroy the frozen protective layer of electrolyte (which protects the carbon lining from corrosion). Operating at low temperature may enable the ledge to grow too much and alumina may precipitate, which has various consequences that can lead to the destruction of the cell.

Thermal inertia allows only “small” variations of power consumption, since the temperature range is still quite limited. However, the current going through this electrolytic bath is around 300–600 kA, the voltage of a cell is 4–4.6 V, and there are 150–288 cells in a single line. The total power consumption of a line is therefore between 200 and 800 MW (almost equivalent

to a large-scale nuclear power plant). Small variations actually corresponds to several MWs, which correlates to grid-scale regulation, although those MWs may not be available for long consecutive periods of time.

Current density is the first lever to perform load management in aluminum plants. If it is usually between 0.8 and 1.0 A/cm², it can be increased to accelerate the quantity of aluminum produced per cell. On the other hand, decreasing it improves current efficiency, and the process consumes less energy per unit of aluminum produced. However, the cost of the saved energy has to be balanced with the fact that a decreased current density increases capital and labor costs.

As for load management through voltage regulation, it is more complicated insofar as it is determined by the reaction itself and the number of cells. Several cells could be short-circuited for small periods of time, but it is economically very inefficient. What could be possible would be to activate a parallel set of anodes, without cathodes, so that the anode reaction becomes:

This anode reaction requires a much higher voltage and increases the acidity of the electrolytic bath, but it is mentioned in this article to highlight that other anode reactions could be considered if economic incentives for grid stabilization were created. In that case, investments may be extremely expensive.

Finally, planning could also be an important source of aluminum plants load regulation. For instance, the replacement of used carbon anodes could be conducted during peak hours of grid electricity consumption, or it could be focused on Spring and Autumn, where electricity consumption is reduced.

Considering their huge energy intensity, aluminum plants are already used in different parts of the world for grid stabilization, even if it is only done so far for small and very short term power consumption variations, like in Alcoa's Warrick operation plant (Choate and Green, 2003). This aluminum plant, which usually consumes at steady-state 500 MW, regularly supplies about 15 MW of fast and short-lasting load management for grid stabilization.

Chlorine production

The global production of chlorine reached 65 Mt. in 2018 (Lazonby, 2018), of which 11 Mt. was produced in the USA and 10 Mt. in Europe. Most of chlorine global production is obtained through the Chlor-Alkali process (Mansfiel et al., 2000), which can be performed with three different kind of cells. Historically, the mercury cell process has been the most predominant, but it has been slowly replaced by the diaphragm cell process and then more recently by the membrane cell process. In 2018 in Europe, the mercury cell process completely disappeared due to its large energy requirements, about 3.7 MWh/t of produced chlorine, and concerns of mercury pollution. This shift leaves the membrane process with a share of 85% and the diaphragm process with a share of 10%, with the remainder coming from other processes where chlorine is a by-product, such as sodium production through Down's process (Eurochlor, 2019; Corrosion-doctors.org, 2019). In the US, the situation is similar (Lenntech.fr, 2019). The energy consumed by the membrane cell process is about 2.5 MWh/t whereas the diaphragm cell process consumes around 2.9 MWh/t of chlorine (Chlis-tunoff, n.d.), which also explains why it is slowly being replaced by the membrane cell process.

This article therefore only focuses on the Chlor-Alkali process performed with membrane cells. The global production of chlorine, 65 Mt./year, represents 162.5 TWh of electrical energy (0.7% of the world electricity consumption); in Europe it represents 25 TWh, and in the USA, 27.5 TWh. Those figures, even if lower than for aluminum production, make chlorine production a good candidate for grid stabilization, because it may still be economically relevant for a given chlorine plant, and at the country scale, the order of magnitude of those numbers is sufficient for considering grid stabilization.

The Chlor-Alkali process with a membrane cell is, as aluminum smelting, an electrolytic process. The input is a constant flow of concentrated pure brine, which can quite easily be obtained from purified seawater so it only contains sodium and chloride ions, which are, in other words, dissolved common salt. This flow fills a tank in which the anode and the cathode are immersed, separated by a membrane, the input flow being on the anode side. The membrane, which only lets water and cations through, is the main difference with a diaphragm cell (which uses a diaphragm instead of a membrane), as the diaphragm only prevents counterflowing. With a voltage of around 3.1–3.3 V between the two electrodes, the following reactions occur:

Dichloride is a gas that is collected through an appropriately placed pipe above the anode side of the brine tank. On the other side of the tank, dihydrogen is collected with a similar system. There is also an output flow that compensates the input flow so the pressure in the tank does not increase. This flow is made of a concentrated solution of caustic soda, since sodium cations go through the membrane to electrically balance the tank, and hydroxide anions are created by the reaction on the cathode side. In the case of a membrane cell, it is already pure and therefore very valuable, whereas a diaphragm cell allows some chloride anions to reach the output flow. The Chlor-Alkali process consequently produces three valuable output products: dichloride gas, dihydrogen gas, and concentrated caustic soda.

The potential of chloride production for grid stabilization is yet to be discovered, since its lower energy intensity relative to aluminum production has driven it away from concrete experimentation. The first source of flexibility that chloride production could offer would simply consist in varying the cell current. Usually, the number of cells in a line, and therefore the total current in the plant, is optimized to obtain a good compromise between the amount of chloride produced per hour and the Joule losses. However, nothing seems to prevent the current per cell to increase or decrease by a few percent, provided that the input flow is also adapted. An increase in current, and therefore in Joule losses, would be partly compensated by faster and more important chloride production, and vice versa. This would result in a possibility for short-term load variations just as in aluminum production.

Moreover, chloride production could offer a better source of flexibility for grid stabilization by introducing a flow of pure oxygen on the cathode (Chlistunoff, n.d.). In fact, this would change the cathode reaction to $O_2 + 2H_2O + 4e^- \rightarrow 4H_2 + 2HO^-$, which has a potential of 1 V less than the original cathode reaction. As a consequence, this modification could result in a decrease of one third of the total energy consumed by the chloride production plant, without any duration limits. The drawback is that not only oxygen is consumed at the cathode, but dihydrogen is not produced, so the oxygen flow should only be triggered when providing grid stabilization flexibility is sufficiently valued so it becomes profitable to consume oxygen and not produce dihydrogen. In terms of grid stabilization, there is another flexibility source that could be employed: dihydrogen can easily be converted in electricity through a fuel cell, with good efficiency. Storing hydrogen can therefore be equivalent to storing electricity, as is described later in this article. Once again, electricity storage comes with very few technical constraints. Those two features underline that chloride production has a great potential for grid stabilization, despite the additional investments they may require.

Magnesium production

The global magnesium production has continued to decrease over the past few years (Bray, 2019). In 2018, it reached almost 1.1 Mt. (Bray, 2019; Essentialchemicalindustry.org, 2016a), with almost 90% of it being produced in China. The limited world production of magnesium means that if a new design is needed to achieve grid stabilization using magnesium production plants, the economies of scale would be limited, but that does not mean that grid stabilization could not be economically profitable for the owner of one particular plant, or technically profitable for a local electrical grid.

There exist two main industrial processes to produce magnesium: the Pidgeon process, which is a thermal reduction process mostly used in China with dolomite ore as input, and an electrolytic process used in the US with brine containing magnesium cations as input, such as at the Great Salt Lake facility (Tripp, 2009). To illustrate that there are actually few magnesium production plants around the world, it can be inferred from (Bray, 2019; Essentialchemicalindustry.org, 2016a; Tripp, 2009) that the Great Salt Lake plant alone produces almost 10% of all magnesium produced globally each year. The electrolytic process could be used for grid stabilization, as discussed for aluminum and chlorine production, if locally needed by the grid, with short-term variations of current. However, this article focuses on the most used process, the Pidgeon process, even if its inherent carbon dioxide emissions may not enable it to remain relevant for the long term.

The Pidgeon process takes dolomite ore as input: $MgCO_3 \cdot CaCO_3$. The first step is calcination, which consists of separating gaseous carbon dioxide from solid dolomite in a kiln at around 1300 °C. Only solid magnesium and calcium oxides are then left.

The second step consists of adding solid silicon to magnesium and calcium oxides to separate them, since, at around 13 Pa and 1200 °C (Rizley and Petersen, n.d.), the magnesium is produced as a gas whereas calcium combines with silicates:

Even though the partial pressure of magnesium is 1 atm at 1800 °C, removing the magnesium vapor produced with powerful electric pumps enables high yields, as well as very pure magnesium, up to 99.99%. Magnesium is then cooled down and forged into ingots.

Although the Pidgeon process itself does not consume electricity directly, electricity consumption is a non-negligible part of the process input. Since reactions occur respectively at 1300 °C and 1200 °C, it can be deduced that this temperature is not achieved with heat pumps, whose efficiencies would be too low at such temperatures. Consequently, the only significant electricity consumption in the process comes from the vacuum pumps that enable the second reaction to occur at 13 Pa.

The electricity consumption of those pumps can be adapted very easily, on short and long periods of time, with simple electronic components. At higher than nominal consumption, yields would increase, but this requires a stronger design for the pumps and the vacuum chamber. At lower than nominal consumption, yields would decrease (reaction could even stop at some point), but this requires no special design. The major drawback of this latter opportunity is that there would remain huge thermal losses since the process occurs at 1300 °C; the fuel needed to maintain such temperatures may create costs above the benefits obtained through grid stabilization. Consequently, only short-term load variations should be considered.

In conclusion, electricity consumption of magnesium production plants, whether it comes from the Pidgeon process's pumps or the electrolytic process, can only be adapted on short term horizons, as for aluminum production, because of thermal losses (the electrolytic process takes place at 1000–1200 °C). The rather significant carbon dioxide emissions of the Pidgeon process, however, make it a strange candidate to perform grid stabilization that is mostly needed because of the integration of renewables.

Titanium dioxide reduction

Titanium dioxide is mostly used pure, as a non-toxic white pigment. However, around 5% is transformed into titanium sponge (Seagle, n.d.), which is pure titanium manufactured in a sponge-like structure. The most common process to do so is the Kroll process, although other processes such as the Armstrong process exist, in this case to produce high-purity titanium for electronic applications, as in the American plant located in Salt Lake City, Utah (Bedinger, 2019).

In 2018, 190 kt of titanium sponge were produced worldwide, mostly in China (37%), Japan (27%) and Russia (21%) (Bedinger, 2019). The electricity consumption of the Kroll process is roughly 15 MWh/t (Kosemura et al., 2002), which results in an annual global electricity consumption of 2.85 TWh. This last figure is extremely low compared to the electricity consumption of any industrialized country, but as discussed for magnesium production, there could exist local technical and economic incentives that could make grid stabilization through titanium production plants relevant.

The Kroll process is a three-step chemical process that makes titanium sponge out of titanium dioxide (which is already the result of a chemical process, as it is rarely found at sufficient purity in nature) (Essentialchemicalindustry.org, 2016b):

1. The first step is the carbo-chlorination of titanium dioxide, which takes place in a chlorinator at around 1100 °C. The reaction being very exothermic, cooling is needed to keep the temperature at its nominal value.

2. The second step consists of purifying titanium chloride. This step is performed mostly by simple distillation, even if additional chemical treatment is needed to remove contaminants such as vanadium oxychloride (VOCl_3), whose boiling temperature is too close to titanium chloride's. The result is 99.9% pure titanium chloride.
3. The final step is the exothermic reduction of titanium chloride into titanium sponge. This step is accomplished by adding liquid magnesium to liquid titanium chloride at a temperature of 1100 °C, which must be maintained by cooling. The atmosphere must be free of all nitrogen and oxygen since titanium sponge is very porous and reacts strongly with those gases. Nitrogen inclusions are the first cause of impurities in titanium sponges (Kosemura et al., 2002; Madehow.com, 2019). Consequently, an atmosphere of argon must be maintained during the whole reaction.

Even at 1100 °C, the last reaction is quite slow; this reduction step can take up to four days for an 8-ton batch (Kosemura et al., 2002).

In parallel to the Kroll process, magnesium chloride is recycled through electrolysis into magnesium and dichloride. This parallel step accounts for 60–70% of the electricity consumption of the Kroll process (Kosemura et al., 2002). The opportunity for grid stabilization with titanium production therefore first comes from magnesium production's grid stabilization opportunities, which are described in the previous section of this article.

As for the rest of the process, the electricity consumption is too diffuse to clearly identify the opportunities. Nevertheless, the Kroll process is the first batch process described in this article. Each batch taking a few days, the electricity consumption could be synchronized with periods of the week/month/year where other sources of consumptions on the grid are low, or simply where the services they can provide are most needed.

Titanium sponge is rarely directly used after the Kroll process: after being crushed and mechanically compacted, it is forged into ingots in a vacuum electric arc furnace. Electric arc furnaces are the subject of the final section of this article. However, titanium production highlights the strong links between all the industrial processes described in this article: titanium dioxide reduction involves magnesium dichloride electrolysis (which produces magnesium and chloride) as well as electric arc furnaces. In terms of grid stabilization, this opens a door for seasonal load variations. In fact, (Bedinger, 2019) underlines the fact that titanium production plants don't operate at full capacity all year long (capacity is 293 kt/year, which is 154% of annual production). As a consequence, titanium production could be performed during periods of the year where residential and commercial electricity consumptions are low. This would result in the fact that magnesium and chloride production and electric arc furnaces would also be more used in such times of year, reinforcing the load management service provided. In general, by planning the production of oversized industries over the year, a more constant electricity consumption could be achieved all year long, which is a valuable service for grid stabilization.

Hydrogen production

Hydrogen production has been thoroughly studied over the years, as it appears to offer an extremely valuable service that science has been struggling to achieve for decades: electricity storage at grid scale, and at all time scales. This trend has several sources:

- Hydrogen is the most abundant element in the universe (IEA, 2019b), and, in particular, it is present in water, which is not a scarce resource on Earth.

- It is possible to extract hydrogen from water with electrolysis, and it only produces oxygen as a byproduct.
- More importantly, it is possible to convert hydrogen back to electricity by combining it with oxygen, which is also an abundant resource on Earth, with only water as a byproduct. The complete reaction is as follows:

However, when looking at world hydrogen production, the situation is quite different. First, hydrogen production was already described with regard to chlorine production: the 65 Mt. of chlorine produced in 2018 only correspond to 1.8 Mt. of hydrogen, whereas the global production of hydrogen is above 70 Mt. (IEA, 2019b). In fact, 50% of hydrogen is produced by Steam Methane Reforming (SMR), 30% by other hydrocarbon reforming, and 17% by coal gasification, which only leaves less than 3% for electrolysis and other methods (Grandviewresearch.com, 2018).

This current situation comes primarily from the fact that electrolysis is not energy-efficient, and therefore not cost-efficient. Electrolysis is actually 3–10 times more costly than SMR (Raissi and Block, 2004), mostly because its energy requirement is around 4.9 kWh/Nm³ of hydrogen produced, whereas SMR can consume as low as 2 kWh/Nm³ of hydrogen produced. The other hydrocarbon-based processes have intermediate energy requirements. However, high-temperature electrolysis could be a great opportunity to produce hydrogen at lower costs, especially if the temperature is obtained using nuclear reactors or solar concentrators (O'Brien et al., 2010; Ayre, 2013).

This efficiency issue is further challenged if the full cycle, converting electricity to hydrogen and then hydrogen back to electricity, is considered. Consequently, other end uses of hydrogen are considered so that hydrogen production may present a good opportunity for upward load variations. There are two main ways to do so:

- Hydrogen can be used as a reducing agent instead of carbon or carbon monoxide, for instance in the making of iron from iron oxides (Chatterjee, 2012). This possibility is all the more interesting as the process produces only water as a byproduct with hydrogen, instead of carbon dioxide. Besides, hydrogen is non-toxic gas, whereas carbon monoxide is extremely dangerous.
- Hydrogen, if combined with carbon monoxide, can produce liquid hydrocarbon fuels through the Fischer Tropsch (FT) process (Leibbrandt et al., 2013), which can be summed up by the following reaction:

To produce the alkanes ($\text{C}_n\text{H}_{2n+2}$) typical to diesel fuels, n should be around 10. Even with catalysts, this requires the reaction to be performed at relatively low temperatures, and therefore to have low kinetics. The FT has many advantages: it is quite efficient, the hydrocarbons it produces can be stored easily, and it produces hydrocarbons which may be still be needed in a zero net emission system, for planes or trucks. Nevertheless, it requires carbon monoxide as input, and all the industrial processes that produce it burn fossil fuels. In fact, carbon monoxide can also be obtained from the electrolysis of carbon dioxide, which may be widely available as carbon capture devices spread, but this is still early research.

Since hydrogen production may prove to be useful on an industrial scale, it is possible to look into the potential for grid stabilization via the processes that make it. First, SMR is a thermal process with methane and heat as inputs. At a temperature of 700–920 °C and at a pressure of 20–30 bar (Sciencedirect.com, 2015), this process produces synthetic gas containing mostly hydrogen and carbon monoxide:

This reaction is endothermic. However, as the temperature falls to around 200 °C, another reaction occurs: the Water Gas Shift Reaction, which is exothermic.

Since almost no electricity is involved in SMR, it has no potential for grid stabilization.

As for the electrolytic process, this article highlights the potential of high-temperature electrolysis (Doctor et al., 2004), for it is the electrolytic process with the highest efficiency. It relies on the following reactions, which occur at around 800 °C:

As high temperature electrolysis is not yet an industrial process, only assumptions can be made on its potential for grid stabilization. First, it probably shares with the other electrolytic processes described in this article the potential for short-term load variations by varying the current of each electrolytic cell. However, this process could be valuable only if coupled with a solar thermal power plant or a nuclear plant since it could consume waste heat, or evacuate heat that is not needed to be converted to electricity for the grid. If a design enabling this were available, it would probably allow longer term production variations of the solar or nuclear power plant, as well as more flexible control of the output of the plant since it has more adaptable technical constraints (especially in the case of nuclear power plants). Grid stabilization through hydrogen production would then be achieved in a very indirect way, far from the perfect storage it seemed to be able to provide at first sight.

Electric arc steelmaking

Electric Arc Steelmaking (EAS) is performed in Electric Arc Furnaces (EAF) and produces pure steel ingots from scrap steel. This process represents 28% of the global production of steel (Worldsteel.org, 2019), the remaining 72% corresponding to blast furnaces in which iron ore is converted to steel ingots by burning oxygen and fossil fuels. Consequently, EAF represents the recycling of used steel parts, whereas blast furnaces are the primary production of steel from ore. Total world production of steel reached 1817 Mt. in 2018 (Worldsteel.org, 2019), including 509 Mt. through EAF. If the increasing global need for steel still limits the share of steel recycled with EAF, it is expected to grow, especially since producing 1 t of steel produces 1.82 t of carbon dioxide on average and EAFs are much less polluting than blast furnaces.

The average electricity of consumption of EAS is around 640 kWh/t of steel produced. This represents a global electricity consumption of 325 TWh, which is 1.5% of the world electricity consumption, or the electricity consumption of the United Kingdom. If all steel was produced through EAF, its electricity consumption would reach 1163 TWh, which is 5.3% of the world electricity consumption. This is the first reason why EAS should be considered on a grid stabilization perspective.

Moreover, typical EAFs consume between 10 and 100 MW (Boulet et al., 2003). If an EAS plant is composed of several EAFs, its electricity consumption can be comparable to the production of typical conventional power plants (coal or gas power plants for instance). As a consequence, EAS plants have the potential to provide huge services for the electricity grid, by consuming or not, since they can provide load variations corresponding to the size of a conventional power plant.

The process of EAS itself is quite simple. After loading a relevant mix of scrap steel in a hearth made of fireclay bricks, with a lining of magnesita-carbon resin bonded bricks, a water-cooled roof is placed on top to form a closed tank. Three carbon electrodes are inserted through the tank roof (for AC EAFs which are the most common type, but there also exist DC EAF where only one electrode is needed, the second one being the hearth itself, but this only works with small hearths) (Wondris et al., 2019). The scrap steel is then melted using electric arcs between the electrodes at temperatures around 1600–1800 °C. In fact, oxyfuel burners are also used to homogenize the temperature in the hearth by burning natural gas in pure oxygen, since hot spots appear behind electrodes. The voltage between the electrodes progressively increases as the electrodes go through the scrap steel mix, until a long stable electric arc is achieved, as Fig. 5 illustrates.

The melted mix obtained then requires a refining step. Oxygen is injected in the hearth, and it combines with the elements with which it has the best affinities, such as phosphorous, sulfur, silicium, magnesium and carbon, before it combines with iron itself. Those oxides form a slag in which carbon is injected and will combine in priority with iron, so it leaves the superficial slag to sink in the core of the melted mix. For impurities such as nickel or copper, they have to be removed by other chemical processes or simply by selecting well the steel scrap before loading the hearth.

Given the previous description of the process, the electricity consumption of EAF is quite complicated to handle for the grid: it is subject to huge and fast variations, and it can go from zero to several hundred MWs in the same day. The fact that the voltage can be controlled suggests an opportunity to provide grid stabilization services without new designs, but this voltage seems to be

Fig. 5 Diagram of an electric arc furnace. Reproduced from Allied Mineral Products (2020) *Electric Arc Furnace*. [online] Available at: <https://alliedmineral.com/solutions/steel/electric-arc-furnace/> [Accessed 8 Jan. 2020].

determined more by the content of the hearth rather than by an economically-driven design choice which could be adapted according to the needs of the grid.

Consequently, the main service that EAF can provide consists in planning, whether it is at the scale of a day, month or year, when the batch is processed and the steel is stored. Although it may not appear as a very flexible service for the grid, given the growing share of EAF in steel manufacturing and the huge amounts of electrical power it consumes, especially locally, it could eventually have an influence on grid balance as important as maintenance shutdowns for nuclear power plants.

This feature of EAFs should not be underestimated as they are no longer only used for steel making, but also to recycle an increasing number of different kinds of metal. Plasma arc furnaces, which operate in similar ways, and can reach temperatures high enough to melt titanium are also emerging (Svirchuk, 2011). The order of magnitude of EAFs in electricity consumption may therefore be expected to increase with the development of metal recycling and carbon dioxide emissions' reductions.

Conclusion

Industries can provide many different kinds of services for grid stabilization. Those services can have two purposes: either to solve a locally constrained electricity grid, or balance consumption and production of electricity at grid scale, instead of turning on a thermal power plant or to absorb excess power from variable renewable sources. From the point of view of a given industrial plant, both drivers would consist of changing electricity consumption. However, those load variations can be essentially discriminated according to how fast they can happen, and how long they can last.

In terms of fast and short-duration services, the electricity consumption of several significant industrial processes can be adapted. For most electrolytic processes, the current per cell is the result of an economic optimization between Joule losses (thermic losses) and rate of production, and not a technical constraint. As a consequence, if an economic incentive is provided to offer short-term load variations, electrolytic industrial processes can adapt easily to such needs, as it is already the case in several aluminum production plants worldwide. In emergency cases, short-circuiting several cells can be considered, even if it quickly becomes economically inefficient. Nevertheless, those solutions cannot last long since it relies greatly on thermal inertia.

Another possibility for fast grid stabilization services can come from the use of pumps in several thermal or chemical processes; just like the current in electrolytic processes, the pressure induced by pumps can be the result of an economic optimization between increasing the rate of production induced by evacuating a produced gas, and the sizing and electricity consumption of the pumps. In that particular case, if no thermal inertia is involved, the service can be provided on longer time scales, as long as the sizing of the pumps is still profitable.

For fast load variations required to last indefinitely, there can still be solutions to automatically change the consumption of industrial processes. If voltage is a technical requirement in electrolytic processes, some reactions can be, wholly or partially, changed so that the voltage is lowered or increased in exchange of losing a valuable byproduct, such as hydrogen in chlorine production. This kind of service requires expensive new design, but it manages to combine fast and long-duration load variations.

For forecast grid congestions or imbalances that can be anticipated, industrial processes can usually be planned according to grid stabilization needs. Whether it concerns daily, weekly or seasonal planning, it can be extremely relevant for grid stabilization to accurately create economic incentives for industries to consume electricity when it is less problematic for the grid. This solution is all the more efficient as industries in many industrialized countries are oversized, and therefore do not need to produce at maximum capacity all-year long. Besides, in terms of delay of response, it should be possible to postpone batch processes with only a few hours (or less) notice. At this time scale, the forecast production of renewables can change significantly.

To conclude, this article only discusses variations in the electricity consumption of industrial processes, but their contribution to grid stabilization could go beyond those variations of said "active" power. Grid stabilization also relies on stable voltages, which is the result of local balances of "reactive" power. There exists very little literature on the subject; in particular, "reactive" power consumption and production of industrial processes are not easily available, but there could be equally interesting opportunities in that domain.

Acknowledgments

I would like to thank my mentor at Idaho National Laboratory, J. Stephen Herring, for the opportunity to study this extremely interesting topic with him as well as for the opportunity to write this article.

I also greatly thank my partner Maud, for all the support, including technical support, she provided me and that I highly needed, for writing this article turned out much more complicated than I expected.

Introduction

The first and the lightest element in the periodic table is H_2 . Although it is the most abundant element in the universe, it is present mostly in combination with other elements and hence offers a challenge to its separation. Fig. 1 shows the global demand for H_2 since 1975 for the production of a range of consumables. In the graph “Other pure”, “DRI” and “Other mixed” are specific applications that require mostly pure H_2 , directly reduced iron steel production and demand for applications that use H_2 as part of a mixture of gases, respectively. The demand has been rising steadily and is expected to continue unhindered with the rising population in the developing parts of the world. Another critical area of growth in the future is in transportation—with the advent of efficient and economically priced fuel cells, the use of H_2 to fuel the transport sector will grow substantially in addition to the demand for other applications.

Currently, the majority of H_2 (>90%) is produced from fossil fuels: natural gas, coal, oil, biomass, etc. In the highly efficient steam methane reforming of natural gas, one of the major processes currently used for mass production of H_2 , natural gas is reacted with steam under pressure and high temperature to produce H_2 , CO and small amounts of CO_2 , and subsequently the CO is reacted with steam (water-gas shift reaction) producing H_2 as the main product and CO_2 as a by-product. The impurities are removed through subsequent processing by a suitable method, such as pressure swing adsorption to deliver pure H_2 .

There are two main consequences to the production of H_2 in large scale using the current fossil fuels-based processes—consumption of large quantities of energy and concomitant emission of greenhouse gases (CO_2 and fugitive CH_4). As shown in Table 1, for the conventional steam methane reforming, the required thermal energy is provided by natural gas combustion, which adds significantly to the emission of carbon dioxide (Table 1).

Although the CO_2 emission is ~ 8.0 t/t of H_2 produced (Table 1), in practice it can be much higher. Incorporation of a carbon sequestration step can reduce emissions. The other fossil fuel based H_2 production processes also represent similar if not greater levels of greenhouse gas (GHG) emissions.

Using the high heating value of methane (55.50 MJ/kg), the total minimum energy required can be estimated (based on 2.92 t of CH_4 per t of H_2 produced) as 162 GJ for the production of 1 million t of H_2 (407 GJ/1 MSCF of H_2).

If 95% of the approximate 70 million t of annual global production of H_2 is assumed to be from fossil fuels, then one would derive ~ 600 million t of CO_2 emission to the atmosphere, just from H_2 production. The energy consumed in the form of natural gas is about 11.3 million Terra Joules, an enormous amount. This simple analysis indicates the significance of GHG emissions and energy consumption that accompany the production of H_2 worldwide.

How can such an enormous amount of GHG emission and the use of fossil fuel-based energy for H_2 production be minimized or avoided? Currently, H_2 can be produced using conventional alkaline or PEM (Proton Exchange Membrane) electrolysis without the emission of GHG. Although these technologies are well developed and can produce H_2 at small and medium scale, they completely rely on electrical energy. Obviously, the electricity needs to be produced from non-fossil fuel to reduce the overall carbon footprint. Nuclear and renewable energy sources can be used to produce electricity—the former is a reliable and steady energy source, while the latter can vary quite drastically depending on geographical location, season and weather conditions.

A significant negative impact of H_2 production processes that rely solely on electrical energy is the overall low efficiency achieved in the conversion of the thermal energy to electrical energy using an energy conversion means such as Rankine Cycle, Brayton Cycle, etc. Unfortunately, a substantial loss (60–70%) in the utilization of the thermal energy occurs due to this conversion using conventional commercial nuclear power plants. So, H_2 production processes that rely on thermal or hybrid thermal/electric process have the potential to offer significantly better overall efficiency. Also, if such processes can operate at high temperatures, the efficiency can be further increased due to the thermodynamic advantage gained at high temperatures (Ebbesen et al., 2014). In consideration of this advantage of high temperature operation, a vast amount of research has been undertaken over several decades into the development of high temperature H_2 production processes. More than 100 processes were identified (Brown et al., 2002), and the development of the most promising ones ensued. These processes include thermochemical cycles, high-temperature electrolysis and

Fig. 1 Global demand for H₂ since 1975. The Future of Hydrogen—Seizing Today's (2019) [iea.org](https://www.iea.org/reports/the-future-of-hydrogen). Table 1 Production of H₂ from steam methane reforming.

Operation	Reaction	CO ₂ emission (metric tonnes/metric tonne of H ₂)	CH ₄ use (metric tonnes/metric tonne of H ₂)
Reforming (+ WGS)	CH ₄ + H ₂ O → CO + 3H ₂ CO + H ₂ O → CO ₂ + H ₂	5.50	2.00
Combustion for reforming	CH ₄ + O ₂ → CO ₂ + H ₂ O	1.46	0.54
Combustion for steam production	CH ₄ + O ₂ → CO ₂ + H ₂ O	1.00	0.36
Power production	CH ₄ + O ₂ → CO ₂ + H ₂ O	0.04	0.02
Total		8.00	2.92

hybrid thermochemical cycles. Since these processes require high temperature energy sources for their deployment, high temperature nuclear reactors and/or solar technologies are ideal for coupling. The nuclear reactor technologies under consideration in the Generation IV (GEN IV) International Forum ([Stanculescu, 2021](#)) are potential candidates for coupling with these high temperature H₂ production processes.

More recently, a significant level of interest in small modular reactor systems, substantially based on GEN IV concepts, have evolved for niche geographical deployment for a range of applications including H₂ production ([Reitsma, 2021](#)).

Thermochemical and hybrid thermochemical hydrogen production processes

An extensive search for the best candidate thermochemical cycle for development was carried out in the first phase of a U.S. DOE International Nuclear Energy Research Initiative (INERI) project reported by ([Brown et al., 2002](#)). Criteria such as efficiency, practicality, adaptability to a nuclear heat source were used in the screening process. As the outcome of the first phase of this study, the Sulfur-Iodine (S-I) Cycle was deemed the most promising. Consequently, the S-I Cycle was selected for further development in the latter phases of the project potentially due to its highest projected efficiency, the best-suitability for coupling to an advanced high temperature nuclear reactor ([Futterer, 2021](#)) and the greatest potential for further improvement.

Some of the other cycles, namely Hybrid Sulfur (HyS) Cycle, Westinghouse process, Hybrid Westinghouse process, Mark-13 process, UT-3 process and Copper-Chlorine (Cu-Cl) Cycle ([Williamson et al., 1982](#)) have also received significant consideration over the last few decades. To-date, out of all of the thermochemical processes considered for high temperature application, the S-I process has been the most researched globally and promoted through demonstration. The HyS and Cu-Cl Cycles have also been developed to various extents, with the latter receiving significant attention in Canada recently.

Sulfur-iodine cycle (S-I cycle)

Following the initial selection of this process as a potential candidate for development towards industrial application in the US, extensive developments ensued in the United States, Japanese Atomic Energy Agency (IAEA), the French Commissariat à l'Energie Atomique (CEA), the Korean Institute of Energy Research (KIER) and Korea Atomic Energy Research Institute (KAERI), and Institute of Nuclear and New Energy Technology (INET) at Tsinghua University (China). Although the US and France collaborated on the demonstration of the S-I Cycle through an INERI project ([Russ et al., 2012](#)), their interest in this process declined mostly due to

down selection of the high temperature steam electrolysis (HTSE) process for continuing focus. However, JAEA, KAERI/KIER and INNET continued their development of the S-I process and resolved many of the technical issues through extensive fundamental and engineering studies.

A pictorial view of the S-I Cycle is shown in Fig. 2 and a simplified schematic is provided in Fig. 3.

In the Bunsen reaction section, SO_2 and I_2 react with H_2O to produce H_2SO_4 and HI . The product solution is separated spontaneously into $\text{H}_2\text{SO}_4\text{-H}_2\text{O}$ solution and $\text{HI-I}_2\text{-H}_2\text{O}$ (HIx) solution. In the H_2SO_4 section, impurities of iodine compounds are removed from the $\text{H}_2\text{SO}_4\text{-H}_2\text{O}$ solution by reverse Bunsen reaction and vapor-liquid separation. Then, H_2SO_4 is concentrated by H_2O vaporization. The concentrated H_2SO_4 is decomposed in two steps; H_2SO_4 vaporized and decomposed into SO_3 and H_2O in the first step and the SO_3 is decomposed into SO_2 and O_2 in the second step. The SO_2 and O_2 in the product gas stream is returned to the Bunsen section, from where O_2 exits as the main potentially valuable by-product of the process. In the HI separation subsection, purification of the HIx is carried out first by removing minor sulfur compounds for subsequent separation of HI . If the HIx solution is distilled to remove HI without any concentration, an azeotropic mixture of $\text{HI-H}_2\text{O}$ is vaporized because the solution is hypo-azeotropic. Hence, a method for HI pre-concentration is critical to avoid excessive energy consumption in HI distillation. Since an energy-efficient method of pre-concentration of HI is required upstream of distillation, an important innovation in

Fig. 2 A pictorial view of the S-I Cycle.

Fig. 3 A simplified schematic of the S-I Cycle (Kasahara et al., 2014).

the form of electro-electrodialysis (EED), first proposed by Onuki et al. (2000), was implemented by JAEA to concentrate HI to hyper-azeotropic. In the EED cell, HI in the solution is dissociated to proton (H^+) and iodide ion (I^-). Iodide ion (I^-) in the anolyte is electrochemically oxidized to I_2 at the anode. H^+ in the anolyte permeates through the cation exchange membrane to the catholyte. I_2 in the catholyte is electrochemically reduced to I^- at the cathode. Consequently, HI in the catholyte is concentrated to hyper-azeotropic to avoid excessive consumption of energy in the subsequent distillation step.

EED technology was further developed and demonstrated in the form of a stack of cells by INNET in 2014, at their demonstration of the S-I Cycle in the IS-100 facility designed for 60 NL h^{-1} H_2 production (Zhang et al., 2018). HI from the distillation column is catalytically decomposed at $350\text{--}450^\circ\text{C}$ into H_2 and I_2 . The product I_2 and remaining HI are separated from the product gas and returned to the Bunsen section and the HI separation subsection, respectively. Small amounts of HI and I_2 in the remaining gas is captured into water, which is fed from outside to compensate for the H_2O consumption as H_2 and O_2 products. Remaining H_2 is obtained as the product of S-I process.

Development of catalysts for HI decomposition is one of the most intensively investigated aspects of the S-I process. Mainly, Pt based monometallic and multi-metallic catalysts supported on a range of support materials have dominated as potential catalysts for this application. Based on these results, Pt-Ir/activated carbon was selected as the catalyst for HI decomposition in the closed-cycle S-I experiment in INNET's Integrated Laboratory System (ILS) (Zhang et al., 2018), with good activity and stability. However, verification of long-term stability of HI decomposition catalysts is still pending.

The decomposition of H_2SO_4 is a common reaction step of the sulfur-family of thermochemical cycles. This reaction is composed of two steps: thermal decomposition of H_2SO_4 to SO_3 and H_2O at approximately 450°C and decomposition of SO_3 to SO_2 and O_2 at $\sim 800^\circ\text{C}$. Since the latter reaction is kinetically slow and carried out at very high temperatures, there have been extensive investigations into catalyst performance and decomposer design. The general conclusion has been that Pt supported catalysts offer the best performance and acceptable stability followed by Fe_2O_3 -based transition metal catalysts. Any instability observed of the catalysts has been attributed to the formation of sulfate, agglomeration of catalyst particles, and the decreasing specific area during the process.

A Bayonet-type decomposer design Fig. 4 (Corgnale et al., 2020) integrating both decomposition steps has been adopted by most groups working in this area. This design enables effective management of heat between the two reactions efficiently. H_2SO_4 solution is fed at the bottom of the outer manifold of the decomposer with the solution rising through the space between the inner and outer tubes of SiC and is vaporized by heat from outside. The decomposition of H_2SO_4 into SO_3 and H_2O occurs in

Fig. 4 Bayonet type H_2SO_4 Decomposer (Corgnale et al., 2020).

the lower temperature bottom section of the outer shell and the rising vapor is decomposed in the catalyst section with further heating provided externally as well as the product gases exiting downwards through the inner tube. The requirement for the very high temperature for the decomposition of SO_3 to O_2 and SO_2 necessitates a very high temperature heat source such as very high temperature gas cooled reactor or high temperature solar thermal technology.

Various efforts have been undertaken to develop effective simulation tools for designing and optimizing the S-I Cycle flowsheet and operational parameters, as well as for evaluating energy consumption. In general, Aspen Plus has been commonly used as the platform for this purpose with custom built thermodynamic data packages for phase separation, H₂ distillation, and EED.

Although the long-term continuous and stable operation of the closed-cycle S-I process still remains a challenge because of several engineering and technical difficulties, several closed-cycle loops have been built and operated for short periods over the last two decades. These include the Lab-Scale Integrated Experiment by the United States and France (Russ et al., 2012) designed for 100 L h^{-1} H_2 production at up to 20 bar pressure; Japan's integrity test facility designed for 200 L h^{-1} H_2 production and selection of engineered materials; China's INNET Integrated laboratory-scale S-I facility designed for 100 L h^{-1} H_2 production; and Korea's S-I integrated facility designed for high pressure operation and 50 L h^{-1} H_2 production (Shin et al., 2015). As part of the down-selection effort, Russ and Buckingham (2009) derived a thermal efficiency of $\sim 38\%$ for the S-I H_2 plant assuming a 40% electrical conversion efficiency for a Next Generation Nuclear Power (NGNP) plant coupled to the S-I plant.

Hybrid copper-chlorine cycle (Cu-Cl)

Following the initial identification of this cycle as a potential process for large-scale production of H_2 using moderate temperature nuclear reactor systems, Argonne National Laboratories, under the leadership of Michelle Lewis, examined several cycles based on the Cu-Cl chemistry (Lewis et al., 2003) and selected the most promising cycles for their research activities. The Cu-Cl thermochemical cycle is a hybrid cycle that uses both heat and electricity to carry out a series of chemical reactions and an electrochemical reaction with the net result being the splitting of water into H_2 and O_2 . The Cu-Cl process is of interest because the maximum required temperature is only 530°C , which means that the thermal requirement of this process can be fulfilled by moderate temperature next generation nuclear reactors such as Super Critical Water Reactors, sodium cooled fast reactor, molten salt reactors, and solar thermal technologies.

Over the last two decades, two variations of the Cu-Cl Cycle have undergone considerable research. In the cycle originally considered for development (Table 2) (Lewis et al., 2003), copper metal is produced electrochemically by the disproportionation of cuprous chloride (CuCl) (Table 2, Eq. 2) in an aqueous HCl electrolyte. Hydrogen gas is then produced by a chemical reaction that takes place between copper metal and gaseous HCl at a temperature of $425\text{--}450^\circ\text{C}$ (Table 2, Eq. 1). The cycle is completed with the steps shown in Eqs. (3)–(5) (Table 2). In the early days of the development of this 5-step Cycle, one of the main impediments to the progress was related to the electrolysis step; dendritic copper growth on the electrode and high voltage resulted in high power consumption. Research activities at AECL in Canada helped to overcome these issues by focusing on the single electrochemical step (Eq. 6, Table 3). It was recognized that the two reactions shown in Eqs. (1) and (2) (Table 2) could be combined/replaced by a single electrochemical reaction that generates H_2 gas directly as shown in Eq. (6) in Table 3. During the last decade, developments in Canada have mainly focused on the 4-step Cycle shown pictorially in Fig. 4 (Eqs. 4 and 5 in Table 2 and Eqs. 6 and 7 in Table 3). The feasibility of each step involved in the cycle has been verified (Naterer et al., 2017) by many groups working on this cycle. Some of the advantages of the Cu-Cl Cycle compared to the S-I Cycle are its moderate temperature requirement, absence of catalyst requirement for the chemical steps, and inexpensive and significantly lower hazardous nature of the chemicals involved. However, the main disadvantage is that there are solid chemicals involved in the cycle and they require special and possibly difficult handling considerations (Fig. 5).

A collaborative project between AECL and the Ontario University (formerly known as University of Ontario Institute of Technology) in Canada produced significant progress within a short time frame towards the development of the cycle through extensive fundamental and engineering studies of all the steps involved in the cycle (Naterer et al., 2017). Naterer et al. (2014, 2015, 2017) have detailed the progress on each of the steps in a series of papers. Li et al. (2020) have detailed the development of the electrochemical step to enable H_2 production at a rate of 50 L h^{-1} at 0.4 A cm^{-2} in a 2.0 M CuCl solution at 80°C using a 100 cm^2 area cell. In addition, studies have led to progress in achieving a significant reduction in the noble metal present in the electrolyser, thus positively impacting the electrolyser CAPEX.

Table 2 Reactions involved in the Cu-Cl Cycle—original 5-step option.

Equation	Reaction stoichiometry	Temperature ($^\circ\text{C}$)	Remarks
1	$2\text{Cu(s)} + 2\text{HCl(g)} \rightarrow 2\text{CuCl(l)} + \text{H}_2\text{(g)}$	425–450	Thermal
2	$4\text{CuCl(a)} \rightarrow 2\text{CuCl}_2\text{(a)} + 2\text{Cu(s)}$	< 100	Electrochemical
3	$\text{CuCl}_2\text{(a)} \rightarrow \text{CuCl}_2\text{(s)}$	< 100	Drying
4	$2\text{CuCl}_2\text{(s)} + \text{H}_2\text{O(g)} \rightarrow \text{Cu}_2\text{OCl}_2\text{(s)} + 2\text{HCl(g)}$	350–400	Hydrolysis
5	$\text{Cu}_2\text{OCl}_2\text{(s)} \rightarrow 2\text{CuCl(l)} + \frac{1}{2}\text{O}_2\text{(g)}$	450–530	Thermal

Table 3 Electrochemical and separation/drying steps of the 4-step Cu-Cl cycle.

Equation	Reaction stoichiometry	Temperature (°C)	Remarks
6	$2\text{CuCl(aq)} + 2\text{HCl(aq)} \rightarrow \text{H}_2(\text{g}) + 2\text{CuCl}_2(\text{aq})$	< 100	Electrochemical
7	$\text{CuCl(a)} + \text{CuCl}_2(\text{aq}) + \text{HCl(aq)} \rightarrow \text{CuCl}_2(\text{s}) + \text{CuCl(s)} + \text{HCl(g)}$	< 100	Separation/drying

**Fig. 5** The 4-step Cu-Cl hybrid thermochemical cycle.

Out of all the steps involved, the hydrolysis step appears to be the most challenging with regard to achieving the performance required to integrate the four steps. Some of these issues are in feeding solid CuCl_2 to the hydrolysis reactor with steam, minimizing the steam to CuCl_2 ratio while maintaining high conversion to copper oxychloride (Cu_2OCl_2). On the other hand, development of the thermolysis step has proven to be less challenging. Significant progress has been reported by [Vega et al. \(2020\)](#) through proprietary developments on all the steps of the process to enable integration of the four steps of the process to produce $50 \text{ L h}^{-1} \text{ H}_2$ during 2021 ([Fig. 6](#)).

[Dincer and Balta \(2020\)](#) assessed the thermodynamic performance of the Cu-Cl Cycle and derived an efficiency of 40–50%, signifying the attractiveness of this moderate temperature cycle for nuclear based H_2 production.

Hybrid sulfur cycle (HyS)

The hybrid sulfur (HyS) Cycle ([Fig. 7](#)) uses both thermal and electrical energy to carry out the two steps, one chemical, the other electrochemical, to achieve the objective of splitting water into H_2 and O_2 .

The H_2SO_4 decomposition step is the same as that of the S-I process, requiring heat from a very high temperature source such as a gas-cooled reactor ([Futterer, 2021](#)) or concentrated solar. Since the H_2SO_4 decomposition is highly developed as part of the S-I process, the main focus of the HyS process development has been on the SO_2 de-polarized electrochemical step. In the 1970s Westinghouse Corporation developed a basic electrolyzer with two compartments separated by a membrane, which was followed by the use of PEM electrolyzer technologies. The HyS Cycle was under considerable development effort in the early 2000 with some critical work led by W. Summers at the Savannah River National Laboratory ([Summers, 2006](#)). Following the down selection of HTSE for

Fig. 6 Equipment representing the 4-step Cu-Cl cycle.

Fig. 7 A pictorial view of HyS process (Roeb et al., 2012).

advancing nuclear H₂ production in the United States, further development of HyS Cycle practically came to a halt in the United States. However, some research activities continued in Europe Roeb et al. (2012) and other parts of the world (Diaz et al., 2019) mostly as basic studies with no known large-scale demonstration planned towards industrialization of the technology.

The conceptual requirements considered by Summers (2006) for the development of the SO₂-depolarized electrolyzer were that the SO₂ is oxidized at the anode at a practical voltage in the range 0.5–0.6 V with high current density operation at 20 bar pressure and 100–120 °C with 50–60 wt% H₂SO₄ without SO₂ crossover. Although the conventional PEM electrolyzer technology was applied, SO₂ crossover issues needed to be resolved. Diaz et al. (2019) have conducted an extensive experimental investigation into the catalysts used on the anode, and reviewed the latest published research in this area to conclude that Pt-based catalysts are the most promising anode catalysts for the SO₂ depolarized electrolyzer even though the performance was still lower than the target of 0.5 A cm⁻² at 0.6 V required for economic application. More recently, Kruger et al. (2015) have reported their studies of various operating methods and electrolyte/electrode parameters for SO₂ electrolysis.

Energy requirements and economics

The cost of hydrogen produced from any process would depend on its CAPEX and OPEX. One of the major components of OPEX is the energy requirement for the process. A rudimentary comparisons of the energy requirement for each method is presented in

Table 4 Energy requirement, capital cost and H₂ production cost per kg.

Method	Thermal energy requirement (GJ/t H ₂)	Capital cost	H ₂ cost (US\$/kg)	Notes
PEM	645	US \$300 M for a 100 t per day H ₂ plant (US \$ 1332/kWe)	2.22 to 9.12	https://www.sciencedirect.com/topics/engineering/hydrogen-production-cost 2016 estimates
S-I	624	US \$2672 M for 400 t per day H ₂ plant	10.71	Allen et al. (2009)
HyS	394	US \$916 M for 360 t per day H ₂ plant	6.83	Allen et al. (2009)
HTSE	359	US \$509 M for 360 t per day H ₂ plant	6.04	Allen et al. (2009)
Cu-Cl	297	US \$131 M for 125 t per day H ₂ plant	4.00	Ferrandon et al. (2008)

Table 4 with the capital cost and the hydrogen cost of production. It should be noted that these values are extremely approximate considering the limited reliability of the assumptions and the low Technology Readiness Level (TRL) development of the advanced production methods. Even for the well-established low temperature PEM electrolyser technology, a review of the CAPEX data revealed very wide ranging values. As a result of the uncertainties in the values, no effort was made to harmonize the data, and the data presented in **Table 4** should be considered only illustrative. The energy requirement for PEM electrolysis is the most reliable value among all values shown. On the other hand, for the advanced production methods, although there has been significant advancements in the developments towards increased efficiency and cost reduction, there is no reliable data available due to technical challenges faced by the developers. It should be noted that the values presented in **Table 4** for the S-I Cycle do not reflect the recent progress that has been achieved in Japan and China on the development of this cycle. Similarly, the efforts in France (EU) and the United States on the development of HTSE technology is expected to positively affect values presented in **Table 4**. For the Cu-Cl Cycle, the developments in Canada is expected to improve on the values shown in **Table 4**. For the low temperature electrolyzer (PEM or alkaline), more reliable CAPEX cost may be obtained directly from manufacturers while the OPEX would depend on the local availability and price of electricity. The references presented in the table provide the assumptions and the validity of the estimates.

Conclusions

In summary, currently, the S-I and Cu-Cl Cycles are being developed with significant global interest for demonstration of integrated continuous operation. Japan and China are continuing with significant progress in the S-I Cycle while Canada is planning to demonstrate the integrated operation of the Cu-Cl Cycle in 2021. Economic application of these processes would ultimately depend on positive outcomes on the overall efficiency achieved (e.g., energy consumption), long-term endurance of structural materials employed for carrying out the chemical steps and the cost of H₂ produced from these processes. The development of all the advanced processes has progressed significantly since the data presented in **Table 4** was published. However, substantial additional progress is required to establish valid CAPEX and OPEX data on these processes before reliable hydrogen production costs can be estimated. However, the recent global activities clearly demonstrate the interest and potential for these processes to become viable methods for eliminating GHG emissions from the conventional hydrogen production processes.

Glossary

Hybrid production plant A combination of two power generation or industrial plants that share one or more energy sources or material inputs and produce variable amounts of energy products to optimize revenue or to meet other time varying objectives.

Integrated energy system An integrated energy system, including hybrid production plants, that is connected by physical or cyber connections and operating in a manner that optimizes any or all of the following objectives; system flexibility and efficiency, revenue, resilience, security, resource stewardship, and environmental sustainability.

Temperature boosting An action that raising the temperate of a given material.

Introduction

Hydrogen is currently used for a wide variety of applications: production of ammonia for fertilizers, hydrodesulfurization of crudes and natural gas, hydrocracking of petroleum, refining low-quality (heavy oil) resources, direct iron reduction, and power generation in a combustion device or fuel cell. Large-capacity hydrogen related energy storage concepts can help accommodate variable power generation sources (wind, solar, hydro) and seasonal periods when baseload power capacity is reduced (e.g., from nuclear and fossil sources) (Mogensen et al., 2019). As such, there has been widespread interest in the development of large-scale hydrogen production technologies. Among the various hydrogen production options, such as low-temperature electrolytic (alkaline and proton-exchange membrane electrolysis), high-temperature electrolytic (steam electrolysis) and high-temperature thermochemical (e.g., sulfur-iodine cycle, copper-chloride) processes, a high-temperature steam electrolysis (HTSE) plant is perceived as a promising flexible load resource (Kim et al., 2018). HTSE that utilizes the thermal and electrical power produced by nuclear reactors has several advantages over other options: non-fossil process, no production of greenhouse gas (GHGs), high electrolysis efficiency due to minimized voltage and current losses (which in turn decrease with increasing temperature), and a less severe corrosive condition under a high-temperature environment compared to thermochemical process (O'Brien et al., 2010; Bo et al., 2010). As a result, in the past decade, there has been a growing interest in research and development on HTSE stacks for producing hydrogen.

This chapter begins with a review of the basic materials, electrochemical physics, and transport phenomena of HTSE cells and stacks, heat management, and controls systems that enable HTSE to optimally exploit nuclear energy. This is followed with a review of recent technical and economic assessments of the value proposition for producing hydrogen using energy generated by nuclear power plants. Next, a description of the application of HTSE within nuclear integrated systems and operation as hybrid plant, and as reversible fuel cell/electrolysis cell units that can firm high penetration of variable renewable energy power generation sources is provided to bolster the role of nuclear energy. The potential benefits of co-electrolysis of steam and CO₂ is covered to provide an understanding of the emerging potential to extend nuclear energy into the transportation and steel making industries. Finally, an overview of commercial advancements and testing underway at institutions around the globe is provided.

Cell makeup and materials

A high temperature solid oxide cell comprises three main components: an electrolyte and two electrodes. The electrolyte is a ceramic membrane that can conduct ions and is sandwiched between two porous electrodes that can conduct. More than three decades have been dedicated to developing oxygen-ion (O^{2-}) conducting electrolyte cells which can be operated in fuel cell mode (SOFC) burning natural gas or hydrogen, or in electrolysis mode (SOEC), splitting steam when the electricity poles are reversed causing the oxygen ion to conduct in the opposite direction (see Fig. 1) [Oxygen-Conducting SOEC].

SOECs are operated in the range of 700–1000 °C and are further capable of splitting steam and CO_2 mixtures into synthesis gas (syngas; $CO + H_2$) (Stoots et al., 2009). Within the past decade, efforts have been intensified to develop a reversible proton-conducting (H^+) electrochemical cells that operate in the range of 400 to 600 °C and can be used to split steam (Fig. 2) (Ding et al., 2020).

A review summary of the state of cell development can be found in Hauch et al. (2020), who remark:

“SOEC technology has undergone tremendous development and improvements over the past 10–15 years. The initial electrochemical performance of state-of-the-art SOEC single cells has more than doubled, while long-term durability has been improved by a factor of ~ 100 . Similar improvements in performance and durability have been achieved on the stack level. Furthermore, SOEC technology is based on scalable production methods and abundant raw materials such as nickel, zirconia, and steel, not precious metals. Performance and durability improvements as well as increased scale-up efforts have led to a hundredfold gas production capacity increase within the past decade and to commissioning of the first industrially relevant SOEC plants. Over the next 2–3 years, plant size is expected to further increase by a factor of almost 20.”

The main factors of consideration in designing a cell are summarized by Minh (2016). Options include choice of:

- Ion-conducting ceramic electrolyte; either O-SOEC or H-SOEC
- Electrode materials; fuel side (either steam/ H_2 or CO_2/CO) and oxygen-evolution side (sometimes referred to as the air side electrode)
- Supporting layer; either by the electrode, electrolyte layer, or a metal-plate; the support must provide mechanic stability to the cell during fabrication, assembly of cells into stacks, and operation of the stacks when thermo-mechanical stresses are exerted
- Geometry; the most common designs are planar with gas and ion mass transport being orthogonal to the plane; cylindrical designs with radial gas and ion transport have also been proven successful
- Coatings that are applied between the electrodes and electrolytes to mitigate reactions and migration of elements between the ceramic layers
- Plates and flow passages for gas distributor and gas collection from the respective electrodes, and which serve to deposit externally supplied heat or remove excess heat that is generated above the thermal neutral point
- Connection of electrical connectors and charge distributors
- Sweep gas for the oxygen electrode, if any
- Hydrogen content added to the inlet steam gas to mitigate Ni oxidation
- Steam content left in the outlet hydrogen stream to avoid hydrogen embrittlement of the cell interconnects.

Fig. 3 illustrates a typical oxygen-conducting cell configuration buildup.

Oxygen-conducting electrolytes

The functional physics of the most common materials used in oxygen-conducting solid oxide cells were first described by Gazzari (2007). The main cell components have not changed significantly in 15 years. For an electrolyte-supported cell, yttria-stabilized zirconia (YSZ) is used. A composite of metallic Ni and YSZ is most often used for fuel side electrode supported cells. The performance of the electrolyte depends on how well it can conduct oxide oxygen ions. Yttria content of at least 8 mol% (connotated as 8YSZ) is needed to fully stabilize the electrolyte composition. Other electrolyte materials with higher ionic conductivity, such as scandia-stabilized zirconia (ScSZ) and various stoichiometries of lanthanum/strontium/gadolinium/magnesium oxides (LaSr-GaMgO), are also receiving significant attention.

Fig. 1 Reversible solid oxide cell operation in electrolysis mode (A) and fuel cell mode (B).

Fig. 2 Proton-conducting solid oxide cell operating in electrolysis mode.

Fig. 3 Typical components in an electrode-supported oxygen ion conducting SOEC.

The compositions and stoichiometries of the oxygen electrode have evolved more over time and can vary according to specific developer cell design and manufacturing objectives and experiences. Strontium-doped lanthanum/manganese oxides (LSM), has evolved to mixed conductors- such as stoichiometries of lanthanum/strontium/cobaltite/ferrite (LSCF) and lanthanum/strontium/cobaltite (LSC) (Hjalmarsson et al., 2014). In order to prevent reactions and species migration (e.g., Y, Zr, La, Sr) between the oxygen electrode materials and YSZ electrolyte, thin layers (0.1- to 5 mm) of gadolinia-doped ceria (CGO) are commonly applied (Ploner, 2019).

Proton-conducting electrolytes

Proton-conducting electrolyte based cells (H-SOEC) represents a promising developing technology for steam splitting. Advantages include conversion at reduced temperatures which helps mitigate thermal cycling stresses on the cells and stacks leading to longer system durability and the possibility of using less expensive materials for the cell metallic interconnects and manifolds. However, the challenge for any H-SOEC is overcoming sluggish electrode kinetics at intermediate temperatures and materials corrosion under high-steam concentration which are noted by Lei et al. (2017) and Grimaud et al. (2012).

An important focus for H-SOEC is the development of a durable oxygen electrode, which bears the rigorous function of splitting the H_2O molecule with efficiencies comparable to fuel side electrodes of an O-SOEC. Currently, both the water oxidation reaction and the oxygen reduction reaction must occur in the triple phase boundary where ion, electron, and gas meet. This requires a mixed ion/electronic-conducting electrode material (referred to as a triple conducting oxide, TCO), and it is further desirable to introduce proton conduction to extend the triple-phase boundary from the electrode bulk to the electrolyte/electrode interface. The work by Dong and Ding at Idaho National Laboratory (Ding et al., 2020, 2018) leads the U.S. Department of Energy efforts to develop H-SOEC materials. Recent research has focused on the creation of a perovskite TCO electrode with a stoichiometry of $\text{PrNi}_{0.5}\text{Co}_{0.5}\text{O}_{3-\delta}$ (PNC) which exhibits relatively high water oxidation and oxygen reduction activity, and excellent durability and thermal cycling capability at reduced temperature range (400–600 °C). In addition to water splitting capability, the potential to

use H-SOECs to abstract hydrogen from ethane and other alkanes which produces hydrogen and valuable ethylene, and higher alkenes that are feedstocks for polymer production, as shown in the equation below, has been proven.

SOEC operating conditions

The ionic conductivity of ceramics is highly dependent on the ceramic temperature and the thickness of the electrolyte. High operating temperatures (700–850 °C) are required to obtain sufficient overall conductivity in the oxygen-conducting electrolyte cells, while the target range for proton-conducting cells is lower (400–600°). The thinner the electrolyte, the higher its ion conductivity and the lower the cell's ohmic resistance and loss of power to joule heating. In an electrolyte-supported cell, mechanical strength is provided if the electrolyte thickness is large (150–250 μm), which leads to relatively high ionic resistance. Therefore, if the mechanical strength can be provided by the steam/H₂ electrode, the electrolyte thickness can be reduced by a factor of 10 or so. The total polarization loss of an operating cell is governed by three dominant factors: activation (or charge transfer) polarization (η_{act}), concentration (or diffusion) polarization which includes chemical reaction polarization (η_{conc}), and ohmic resistance polarization (η_{ohm}). Under the same operating conditions of temperature and current density, a SOFC and a SOEC are likely to have the same ohmic and activation overpotentials. However, the concentration overpotential values are different for the SOEC and SOFC because the gas transport mechanisms through the electrodes are different in two cases.

Fundamental thermodynamics

A comprehensive treatise of the thermodynamics of SOEC is given by O'Brien (2008). In order to electrolytically split H₂O or CO₂ molecules, a voltage must be applied across the cell that is greater than the open-cell potential. The standard-state open-cell potential, V^o , is given by:

$$V^o = \frac{\Delta G_R^o}{jF}$$

where j is the number of electrons transferred per molecule of hydrogen produced. For the steam-hydrogen system, $j=2$, O²⁻ ions are transported through and O-SOEC electrolyte (or $j=1$ for H⁺ ions transported through H-SOEC). The standard-state open-cell potential applies to the case in which pure reactants and products are separated and at one standard atmosphere pressure. In most practical HTE systems, the incoming steam is mixed with some hydrogen and possibly some inert gas. For O-SOEC, hydrogen is required in order to maintain reducing conditions on the nickel cermet electrode. Also, it is not desirable to run the electrolyzer to 100% steam utilization, because localized steam starvation will occur, severely degrading performance. Therefore, the outlet stream will include both steam and hydrogen. Residual steam can be removed from the product by condensation. On the oxygen-evolution side of the O-SOEC, air is often used as a sweep gas, so the oxygen partial pressure is only about 21% of the operating pressure. In addition, the electrolysis system can operate at elevated pressure.

To account for the range of gas compositions and pressures that occur in a real system, the open-cell (or Nernst) potential, V_N , can be obtained from the Nernst equation, which can be written in terms of the cell temperature, T , and pressure, P , universal gas constant, R_u , gas mole fractions, γ_i , for of H₂O, H₂, and O₂, and standard pressure, of P_{std} .

$$V_N = V^o - \frac{R_u T}{iF} \ln \left[\left(\frac{\gamma_{H_2O}}{\gamma_{H_2} \gamma_{O_2}^{1/2}} \right) \left(\frac{P}{P_{std}} \right)^{-1/2} \right]$$

The performance parameter that quantifies the ohmic losses associated with the operation of solid-oxide electrolysis cells is the area-specific resistance (ASR), expressed as:

$$ASR = \frac{E - E_{ref}}{i}, \text{ where } i = \frac{I}{A_{cell}},$$

where E is the applied potential and E_{ref} is the reference or open cell potential, I is the current, A_{cell} is the cell surface area, and i is the current density (A cm⁻²).

Operation of an electrolysis stack is fundamentally different than operation in the fuel-cell mode. From the standpoint of heat transfer, operation in the fuel-cell mode typically necessitates the use of significant excess air flow in order to prevent overheating of the stack. The potential for overheating arises from two sources: (1) the exothermic nature of the hydrogen oxidation reaction, and (2) ohmic heating associated with the electrolyte ionic resistance and other loss mechanisms. Conversely, in the electrolysis mode, the steam reduction reaction is endothermic. Therefore, depending on the operating voltage, the net heat generation in the stack may be negative, zero, or positive.

The ohmic heat flux, q_{Ohm}'' (W cm⁻²), is given by:

$$q_{Ohm}'' = i^2 ASR = i(V_{op} - V_N)$$

where V_{op} is the actual operating voltage of the cell.

The reaction heat flux can be expressed in terms of the Gibbs Energy of Reaction, ΔG_e (J mol^{-1}), and Enthalpy of Reaction, ΔH_R (J mol^{-1}):

$$q_R = i(\Delta G_e - \Delta H_R)$$

The operating point where the ohmic heating equals the endothermic heat of reaction is referred to as the thermal neutral point. This phenomenon is illustrated in Fig. 4 which shows the respective internal heat sink/source fluxes in a planar solid-oxide stack associated with the electrochemical reaction and the ohmic heating.

Operation at or near the thermal-neutral voltage simplifies thermal management of the stack since no significant excess gas flow is required and component thermal stresses are minimized. In fact, in the electrolysis mode, since oxygen is being produced, there is also no theoretical need for air flow to support the reaction at all. In a large-scale electrolysis plant, the pure oxygen produced by the process could be saved as a valuable commodity. However, there are several good reasons to consider the use of a sweep gas on the oxygen side. Materials considerations aside, a sweep gas reduces the average mole fraction of oxygen, γ_{O_2} , thereby reducing the open-cell and operating potentials, resulting in higher electrolysis efficiencies.

As shown presently, operation below the thermal neutral voltage requires heat addition to maintain an isothermal state in the cell. This heat may be added by an external heat source, such as a nuclear reactor.

Synergy with nuclear energy

Thermodynamic synergy between nuclear energy and high temperature steam electrolysis can lead to efficiency gains. The combination of a high-efficiency power cycle and the direct utilization of nuclear process heat can result in overall thermal-to-hydrogen conversion efficiencies of 50% or higher. Electricity conversion efficiencies of over 100% are easily attainable when steam and additional thermal energy are supplied from the nuclear process.

To illustrate the concept of increasing efficiency with direct thermal deposition to an SOEC, O'Brien (2008) plotted the heat flux necessary to maintain an isothermal condition in a representative cell as a function of operating voltage and area specific resistance (ASR, in Ohm cm^2) (Fig. 5). As the operating voltage is raised above the thermal neutral voltage (V_N), heat must be extracted. This can occur naturally as cell degradation increases ASR over time, necessitating increased operating voltage to maintain a constant current and hence a constant hydrogen production rate. Conversely, when the operating voltage is dropped below the thermal neutral point, then heat input is required to maintain the operating temperature. This heat can be conveniently provided by superheating the steam input into the cell, as well as a sweep gas for the oxygen electrode. Although there are many factors to take into consideration, including steam utilization, increased corrosion, and the kinetics of cell operation, cell operating parameters can be optimized through integrated materials selection, stack design, and integrated systems engineering.

The plot in Fig. 6 compares the operating voltages of the leading methods for hydrogen electrolysis by water at operating current around 1.5 A/cm (compare Graves et al., 2011). The research goal for advanced alkaline electrolysis (AE) and proton-exchange

Fig. 6 Comparison of electrolysis cell operating voltages to produce one kilogram of hydrogen at 20 bar pressure [SOEC indicates breakdown of kW h^{-1} thermal vs. kW h^{-1} electrical].

membrane (PEM) is to decrease the operating voltage with advanced membranes for efficient hydrogen separation and reduced thermal energy dissipation. The energy for AE and PEM is currently 100% electrical power.

PEM and AE are capable of operating at higher pressure, while an SOEC stack assembly would either require a pressure containment vessel or post process gas compression. The power for hydrogen multi-stage compression is added to the SOEC electrolysis production featured in Fig. 6 to establish parity with the AE and PEM technologies that can already conveniently split pressurized water.

For high temperature steam electrolysis (HTSE) the energy required is split between thermal and electrical power, where thermal power can be provided in four stages, as shown in Fig. 7; (1) steam generation, (2) steam superheating (which can be provided by recuperation from the hot effluent H_2 and O_2 product streams), (3) feed gas temperature boosting and (4) direct heat deposition in the cell to maintain an isothermal operating condition when operating below the thermal neutral point. Waste heat (5) can be recovered for boiler feed water heating. Direct cell or stack heating complicates the stack design; hence, the likely best engineering solution is to raise the inlet gas temperatures with the nuclear reactor source. In case the temperature of the nuclear reactor heat transport fluid is less than the HTSE cell operative temperature, then electrical power can be used (6) to provide the topping heat needed. When an exogenous source of heat is unavailable, electrical heating can be used to generate the steam needed for HTSE; however, the thermodynamic efficiency is greatly diminished.

Fig. 7 Coupling of nuclear energy with high temperature steam electrolysis.

This comparison confirms the advantages of higher thermal dynamic efficiencies of high temperature steam electrolysis; ranging from 25–30% greater energy efficiency overall. In order to achieve higher SOEC efficiencies, thermal energy that is delivered above the operating temperature of the cell must be provided. The Very High Temperature Gas-Cooled reactor is capable of delivering heat in the range of 750 °C (current design) to 950 °C (future design). With the advent of proton-conducting SOEC (P-SOEC), the operating temperature will be reduced to ≤ 600 °C. At this operating temperature, the heat delivered from the emerging class of molten salt and liquid-metal cooled reactors can be coupled with P-SOEC to realize the benefits of water splitting with a primary heat source.

Economics of high temperature steam electrolysis

In recent years, Idaho National Laboratory has led efforts to evaluate the costs of low temperature and high temperature steam electrolysis with the express interest of coupling nuclear power plants to hydrogen production. The traditional method of reforming natural gas to produce hydrogen (i.e., steam/methane reforming; or SMR) currently enjoys the benefit of historically low prices due to the surplus of natural gas production in the United States, Russia, and locations in Africa and the Middle East. Similarly, the cost of producing H_2 by electrolysis is a strong function of the cost of electricity, which has dropped with the advent of low-cost solar panels and wind towers along with a buildup of new gas turbine power plants. These factors have motivated nuclear plant owners and the United States Department of Energy (U.S. DOE, 2020a, b), cooperating together, to consider new markets for operating nuclear plants, including especially water-splitting electrolysis options (Frick et al., 2019; Boardman et al., 2019a, b).

The economic proforma presented herein is for a nominally 900 MW electrical power nuclear plant coupled to a greenfield hydrogen plant that is separated 1 km from the nuclear plant. The levelized cost of hydrogen production (LCOH) for a discounted cash analysis was computed when invoking the assumptions listed in Table 1. Wholesale prices of electricity ranging from 25 to 50 \$ $MW h^{-1}$ were evaluated. This brackets the cost of energy production by existing Generation II light-water reactors in the United States, Europe, and elsewhere. Steam purchased from the nuclear facility (also referred to as “nuclear process heat”) was priced at the cost of electricity times the 32.3% thermal efficiency expected for the power conversion system at a typical single-unit nuclear power plant. It effectively equates the cost of heat to the cost of electricity that could otherwise be produced and sold using this heat.

Direct capital costs, as bare-module costs not-including the cost of stacks, for the HTSE process model were estimated using the preliminary plant design developed by Dominion Engineering (Krull et al., 2013). For some equipment items, the Aspen Process Economic Analyzer (Aspentech, 2019) was used to estimate the capital costs. Finally, it is necessary to estimate the cost of stack assemblies that are expendable and must be replaced when the cell degradation reaches a point of inefficient operations. Based on early indications of stack testing using a 25 kWe test stand capability (O’Brien et al., 2020), cell degradation rates of less than

Table 1 Summary of financial parameter used for a discounted cash flow calculation of LCOH.

Description	Value	Comments
Oxygen selling price	0.03 \$ kg ⁻¹	HSTE production of pure oxygen
Nominal IRR	12%	Internal Rate of Return on equity investment
Electricity price (\$/MWh-e)	20, 25, 30, 40, 50	
Thermal-energy (steam) cost (\$/MWh-t)	Varies	Multiple of an electricity price and the thermal-to-electrical conversion efficiency of 32.3%
Capacity market payment (\$/MWh-day)	132.4	
Debt to equity ratio	80% debt, 20% equity	80%/20% debt-to-equity ratio assumes strong government support for clean hydrogen production will apply to the first several electrolysis plants producing clean hydrogen
Debt interest rate	5%	Debt is backed with governments bonds
Debt period	20 years	
Annual inflation rate	1.9%	Based on the average inflation for the past 20 years
Overall tax rate	24.8%	20% federal; 6% state (current average rates applicable in the United States)
Capital depreciation schedule	Standard Modified accelerated cost recovery system (MACRS) depreciation method	Depreciation method, with a property class of 15 years
Decommissioning	10% of total depreciable capital	
Salvage value	10% of TCI	Total Capital Investment
Working capital	10% of the annual change in total operating costs	
Plant construction period	1 year; HTSE	HTSE plants are based on modular units that are factory assembled, reducing the time needed to build out the plant
Start-up year	2025	
Start-up time	1 year	Operating costs and revenues during start-up are 75% and 50% of the total values, respectively
Plant life and analysis period	20 years	Excluding construction time
HTSE Operating Capacity Factor	0.92	Assume nuclear plant and hydrogen plants will undergo coordinated outages/maintenance

From Boardman RD, Kim JS, Hancock S, Hu H, Frick K, Wendt D, Rabiti C, Bragg-Sitton SM, Elgowainy A, Weber R, and Holladay J (2019) *Evaluation of Non-Electric Market Options for a Light Water Reactor in the Midwest*. INL/EXT 19-55090.

0.5% per 1000 h of operations can be expected. For the current cost calculations, it was assumed that cells would be replaced when performance drops to around 80% of initial operating output. Hydrogen production rates and associated steam utilization factors were taken from estimates identified by O'Brien (2008).

A critical parameter for the current cost estimation is SOEC stack manufacturing costs. Currently, no manufacturing plants have been constructed; therefore, the cost of stacks at full commercial capacity were estimated from SOFC stack manufacturing experiences and technology providers. The cost of stacks is currently being debated. For the HTE plant, the baseline SOEC stack cost considered was \$50 kW⁻¹ (direct current [DC] power input to SOEC). This stack cost is based on input from Krull et al. (2013) and is assumed possible when high-volume manufacturing is achieved; namely for a scale of at least 500 MW of annual electrolysis stack volume (Boardman et al., 2019b). Notwithstanding, the cost of hydrogen production is not strongly correlated to stack manufacturing costs; rather it is more important the stacks are durable and remain effective for at least approximately 40,000 h of operation. Here stack costs of \$75 kW⁻¹ (+50% baseline) and \$35 kW⁻¹ (−30% baseline) were considered to reflect an expected spread in the cost of SOEC.

The SOEC plant matching the 900 MW nuclear plant is 578 t d⁻¹ (or 534 t d⁻¹ based on a 92.4% OCF). The divided power duties are 846 MW-electrical and 192 MW-thermal, respectively. Such a world-class scale would provide H₂ to multiple industries and is defined as a “large-scale” (or high-volume) production case in this analysis. Preliminary safety risks pertinent to locating a large hydrogen plant with appurtenant hydrogen storage within 1 km of a nuclear plant are being considered (Vedros et al., 2020).

Fig. 8 plots the levelized cost of hydrogen (LCOH) versus the cost of HTSE stack costs. The cost of producing hydrogen with an equivalent scale steam methane reforming (StMR) plant is also given for three projected natural gas price scenarios corresponding to industrial natural gas costs in the United States in 2019 (U.S. Energy Information Agency, 2019). The sale of oxygen results in a 0.25 \$ kg⁻¹ reduction in the minimum manufacturing price of hydrogen. Credits for the benefits of avoiding carbon dioxide emissions and other greenhouse gases versus hydrogen production by steam methane reforming can be significant. The evaluation by Idaho National Laboratory shows that each kilogram of hydrogen produced by electrolysis supported with nuclear energy merits 0.01 \$ kg⁻¹ for a CO₂ tax of 1 \$ t⁻¹ CO₂. Therefore, a tax of 100 \$ t⁻¹ CO₂ would increase the value of nuclear-sources hydrogen by 1 \$ kg⁻¹ H₂. This provides a compelling argument for hydrogen produced with clean power.

Dynamic operations of HTSE

Hybrid plant operations

For purposes of terminology, a hybrid plant is defined as a plant that dispatches one or more energy outputs to produce at least two unique products in a manner that optimizes at least one objective such as (1) revenue generation, (2) pollutant emissions reduction, or (3) grid reliability and/or resiliency and/or stability. The marginal price of electricity (P_{marginal}) rises when the demand

Fig. 10 Example of hybrid plant operation dynamics. Source: Frick K, Talbot P, Wendt D, Boardman RD, Rabiti C, Bragg-Sitton SM, Levie D, Frew D, Ruth M, Elgowainy A, and Hawkins T (2019) *Evaluation of Hydrogen Production Feasibility for a Light Water Reactor*. INL/EXT-19-55395.

exceeds supply. This is projected to happen with increasing frequency as variable renewable supply continues to rise. This presents a unique market case for nuclear hydrogen production which takes advantage of market conditions to optimize revenue generation. Fig. 9 illustrates how electricity produced at the marginal electricity selling price could be sold to the grid or used to generate hydrogen. In this case, the systems may be viewed as a “price taker” so far as it will schedule ahead for the power market anytime the marginal electricity price exceeds some price point (referred to herein as the Switch-over Price). When the marginal price of electricity is high, the electrolysis plant is rapidly turned down while dispatching electricity to the grid. Conversely, when the price of

electricity is low, then the plant will ramp up hydrogen production. Naturally, in order to supply hydrogen to a dedicated industrial user, hydrogen storage will be necessary.

Hybrid production of hydrogen leads to an opportunity to deploy a reversible SOFC/SOEC system in which the hydrogen produced below the cutoff-price is stored to produce electricity when the price of electricity rises above the cutoff price.

To analyze the economic viability of hybrid operations, particularly given the uncertainty surrounding load demand, electricity prices, and the availability of variable power generation resources, a stochastic technoeconomic analysis package (Holistic Energy Optimization Network [HERON]) has been developed for use with a risk analysis framework- Risk Analysis Virtual Environment (RAVEN). An example of a predicted 72 h dispatch of power from a nuclear power plant is reproduced here in Fig. 9 for a deregulated market in the United States where the objective is maximum revenue for the plant (Frick et al., 2019; Talbot et al., 2020). In this case, two resources are tracked-electricity and hydrogen- for five components: (1) an electricity source (balance of plant; BOP), (2) a hydrogen production facility (HTSE) that consumes electricity to make hydrogen, (3) an electricity market (Electric Grid) that consumes electricity, (4) a hydrogen storage unit (H2_storage), and (5) a constant hydrogen consumer (H2_market1). The graphs show the operation of each unit in terms of electricity (top), hydrogen (middle), and storage as well as price of electricity (bottom). When the marginal price of electricity is low hydrogen is produced and stored. When the price of electricity near the cutoff price, hydrogen is taken from storage to supply the hydrogen consumer so that all electricity produced can be sold at the grid. The performance over the three-day period illustrates how a general dispatch optimization can optimize the profit for a given hybrid nuclear power plant (Fig. 10).

Physics-based HTSE modeling

Dynamic optimization of a hybrid nuclear/hydrogen plant requires a realistic understanding of the flexibility for modulating the HTSE plant as much as dispatching the thermal and electrical power from the nuclear plant. A physics-based model, consistent with the heat management process flows shown in Fig. 7 was developed by Kim et al. (2018). This model was incorporated into HERON to constrain solutions to the practical operating ramp rates and limits of the plant. The entire system was dynamically modeled with the Modelica modeling language using a commercially available Modelica-based modeling and simulation environment (Fritzon, 2014; Dassault Systèmes, 2017).

The case study and control schemes developed by Kim et al. (2018), showed a coupled nuclear/HTSE plant can respond quickly (on the order of hundredths of a second) with fast ramping capability, settle adequately fast and maintain the required change for a sufficient duration in response to rapid, large load changes of grid generation demands. The dynamic response characteristics of the coupled nuclear and HTSE plants are able to provide various ancillary grid services to manage the variability and uncertainty introduced with high penetration of renewables while supporting large-scale, carbon-free hydrogen production.

Conclusion

High temperature steam electrolysis (HTSE) is a promising method for high-efficiency hydrogen production. HTSE cells currently being developed operate in the range of 750 to 900 °C, but can also be coupled with lower temperature heating sources with minimal loss of efficiency through heat recovery. Hybrid plant operation of a nuclear/HTSE plant can support grid capacity demands by dispatching electricity to the grid when demand exceeds variable renewable generation sources. Hydrogen is produced using heat and electricity that is not immediately needed to meet grid demand. This hydrogen can be sent to an industrial user, or burned in a reversible solid oxide fuel cell (SOFC) and solid oxide electrolysis cell (SOEC), i.e., SOFC/SOEC plant to provide additional electricity back to the grid to meet peak demands.

Efforts to develop robust materials and efficient stacks and systems are achieving the performance standards and durations needed for commercial operations. When high volume manufacturing rates are realized, the capital costs will reach levels that can make electrolysis systems competitive with the incumbent hydrogen carbon reforming processes.

Introduction

Nuclear energy is increasingly being recognized as a valuable low-carbon, low-emissions energy source that can help achieve clean energy targets being set by states, commissions, and utilities in the United States. Currently, nuclear power provides about one-fifth of the country's electricity. Nuclear power plants (NPPs) further provide the grid with all-weather season-long baseload capacity that is important to grid reliability and resiliency. Light water reactor (LWR) NPPs in the United States, like other sources of electricity generation, are facing increasing cost pressure on the electricity grid due to historically low-priced natural gas (NG) and the rapid expansion of solar and wind energy. Solar and wind energy provide spikes on the grid during periods of high production, but there will be a continued opportunity for baseload generators, such as NPPs, to provide electricity to the grid when solar and wind energy installations are producing little output. During times of grid overgeneration the NPP energy can be diverted to create other value-added chemicals and fuels. Therefore, the U.S. Department of Energy (DOE) Light Water Reactor Sustainability (LWRS) Program is addressing flexible plant operations that can diversify the revenue of NPPs.

Previous reports have evaluated opportunities to couple LWRs with hydrogen production (Frick et al., 2019; Hu et al., 2019; Knighton, 2020). This article analyzes several synthetic fuel (synfuel) production pathways that could be coupled with LWRs to provide alternative options to utility companies for using nuclear energy to create value added products during periods of overgeneration of electricity to the grid. A conceptual integrated plant would consist of a hybrid LWR delivering power and heat to a synthetic fuel and/or chemical facility. The synfuels plant would employ co-electrolysis to convert CO₂ and water into syngas (synthesis gas, a mixture of H₂ and CO). The CO₂ ideally would come from a source that is in close proximity to the LWR and one in which the CO₂ is currently being released to the atmosphere, to take advantage of possible clean energy credits. Sources such as an ethanol plant release CO₂ in high concentration which makes the CO₂ separation and utilization more cost effective. In this article an ethanol plant located between 50 and 100 miles from the LWR is assumed to be the CO₂ source. CO₂ sources in close proximity to LWRs, such as a natural gas combined cycle (NGCC) plant, and state-of-the-art carbon capture technology are also possible options. The syngas would then be converted to synthetic fuels via the most economical processes. Choices for the conversion of syngas to synfuels include Fischer-Tropsch (FT), methanol-to-fuels, and ethanol-to-fuels, among others.

Co-electrolysis via a solid oxide electrolyzing cell (SOEC) is assumed in the techno-economic analysis (TEA) detailed herein to take advantage of its high efficiency as compared with a standard polymer electrolyte membrane (PEM) electrolyzer. Although higher value synchems offer compelling investment potential, the focus of the TEA is on production of synfuel blendstocks compatible with existing liquid transportation fuels. The methanol (MeOH) route was selected because methanol is a common and flexible intermediate that can either serve as a base chemical or be converted to hydrocarbon fuel. The plant scale assumed is commensurate with the typical scale used for a cellulosic biorefinery (2000 dry t/day biomass feed) to provide a consistent comparison with renewable fuel from biomass. This is equivalent to a syngas flow of 141 t/day H₂ and 973 t/day CO. Detailed process models and TEA were developed for the CO₂ to synfuel pathway incorporating the use of the LWR heat and electricity as an energy source. Equipment CAPEX and OPEX are detailed in the economic modeling, including reactor and other unit operation costs, and feedstock and product valuations. Sensitivity analysis around key process and economic assumptions is also presented.

Routes for CO₂ to fuels or chemicals

There are many ways to make fuels or chemicals from CO₂. Fig. 1 provides a flowchart of some of the general pathways for producing CO₂-derived fuels integrated with an LWR. Steam and power from the LWR are provided for CO/H₂ (syngas) production in addition to any demand required by the chemical plant. Syngas can be produced from CO₂ via co-electrolysis or the reverse water-gas-shift (RWGS) reaction. Co-electrolysis is preferred over having separate electrolyzers for CO₂ and water as it has been found to be more efficient (Fu et al., 2010). Syngas is used to produce a wide range of fuels and chemicals, including but not limited to synthetic NG, dimethyl ether, methanol, ethanol, and hydrocarbon fuel blendstocks. Compounds such as methanol and ethanol can also be produced directly with co-electrolysis. However, it is thermodynamically unfavorable compared to making syngas, as the

Fig. 1 Overview of various synfuel/synchem pathways integrated with an LWR.

number of electrons needing fixed is 6 for methanol and 12 for ethanol, versus 2 for CO. **Table 1** lists the numbers of electrons required for CO and other chemicals.

Fuels

Syngas can be converted to oxygenated fuels, such as ethanol or methanol, or converted further into hydrocarbon fuels. Ethanol can be produced from syngas through biological or thermochemical means, as shown in **Fig. 2**. Fermentation has been indicated by

Table 1 Number of electrons transferred for converting CO₂ to syngas and chemicals.

Compound	Electrons transferred
Syngas	2e ⁻
Formate	2e ⁻
Methanol	6e ⁻
Methane	8e ⁻
Ethanol	12e ⁻
Octanol	48e ⁻

Fig. 2 Fermentation and catalysis of syngas to ethanol.

many researchers as an efficient and cost-effective method for conversion of syngas and several companies have now made the process commercial. For example, LanzaTech now commercially produces ethanol via syngas fermentation using its proprietary Clostridial biocatalyst. Direct thermo-catalytic conversion of syngas to ethanol is also possible using several different catalysts, as shown in Fig. 3.

Fig. 3 details three alternative pathways for syngas conversion to ethanol that are in earlier stages of development than direct conversion shown in Fig. 2. Fig. 3A shows a direct conversion of syngas to ethanol through dimethyl ether (DME) as a key intermediate, the catalyst $ZnAl_2O_4/H\text{-MOR } ZnAl_2O_4$ produces ethanol with a selectivity of 52% (Zhou et al., 2018). There are some

Fig. 3 Syngas conversion to ethanol via catalysis.

Fig. 4 Syngas to hydrocarbon fuel via Fischer-Tropsch synthesis.

other fuel alternatives, such as DME, which is a clean-burning, non-toxic, potentially renewable fuel that can be produced from methanol. The path of methanol-to-ethanol production is not necessarily the cheapest. Some other tracks with inexpensive catalysts may be worth evaluating, such as methyl acetate. The two-step conversion of methanol to ethanol via the methyl-acetate process is at the stage of pre-commercialization. Fig. 3B details industrial methanol carbonylation to produce acetic acid that is performed either over the Ir-based (Cativa process) or Rh-based (Monsanto process) catalysts (Lu et al., 2016). Fig. 3C shows the methanol conversion process through dimethyl oxalate. In this process ethylene glycol and ethanol can be produced, making it a versatile method for producing essential chemicals (Yue et al., 2014).

Methanol can also be converted to hydrocarbons via the methanol-to-gasoline (MTG) process or the MTO process, both of which were originally introduced by the Mobil Oil Corporation. MTG is carried out over a HZSM-5 catalyst with high selectivity and little side-products, producing a hydrocarbon mixture of narrow compositional range (Gogate, 2019). The MTO process was developed by essentially controlling process conditions to interrupt the MTG methanol to hydrocarbons reaction and has been commercialized by Honeywell UOP (UOP) and others.

Syngas can also be converted directly into hydrocarbon fuel using the established FT process, as shown in Fig. 4. The FT process is the oldest coal-to-liquids technology, invented in the 1920s and used by the Germans during World War II to provide needed liquid hydrocarbon fuels. Several FT-based commercial plants are operating today, including Sasol's Sasolburg coal-to-liquids plant (South Africa). Sasol started developing designs for a gas-to-liquids plant in Lake Charles, Louisiana, but the project was cancelled in 2017 due to the collapse of oil prices which decreased the differential between the NG feedstock and the value of the fuel products (Grisggs, 2017).

Chemicals

Many pathways exist for converting CO₂ to chemicals via thermochemical or electrochemical processes followed by catalysis. CO₂ reduction reactions can yield various valuable multi-carbon compounds including ethylene, acrylic acid, propylene, and C1 chemicals and polymers (Alper and Yuksel Orhan, 2017). As of 2017, 130 Mt. of CO₂ is used annually to generate urea, salicylic acid, polycarbonates, and cyclic carbonates (Koempel and Liebner, 2007). Fig. 5 shows two pathways for converting methanol to propylene or ethylene. The MTO reaction detailed in Fig. 5B is one of the most critical reactions in C1 chemistry, which provides a chance for producing basic petrochemicals such as ethylene and propylene (Eng et al., 1998). The methanol-to-propylene (MTP) process shown in Fig. 5A produces propylene from methanol (Koempel and Liebner, 2007). Significant differences exist between the MTO and MTP processes in regard to reactor design and productivity (Barger, 2002). MTO uses a fluidized-bed reactor, where heat can be removed quickly, and catalysts can be easily regenerated. MTP uses a fixed bed reactor where heat removal is problematic but overcome by using multiple catalyst beds. Fixed bed reactors are easier to scale up compared to fluidized beds, are cheaper and have better product selectivity. However, MTO can use crude methanol whereas MTP must use pure methanol, thus adding to the overall cost for MTP (Jasper and El-Halwagi, 2015). As is evident, the chemical derivatives of ethylene and propylene are numerous and have a variety of industrial applications. Polymerization processes are not detailed here.

Fig. 5 Methanol conversion to chemicals via methanol-to-propylene (A) and methanol-to-olefins (B).

Ethanol is an essential source of many chemical compounds, including para-xylene. Ethylene is the intermediate compound in the process of producing para-xylene, either directly (Fig. 5B), or indirectly (Fig. 6A). In a direct path, ethylene is used in more than one step of a complex process to produce para-xylene (Zhang et al., 2015). In the indirect method, DMF is the primary compound for the production of para-xylene, and ethylene plays a role in forming double bonds (Lyons et al., 2012).

Fig. 6 Ethanol conversion to para-xylene.

As a final note on chemical conversion, formic acid (FA) is a critical commodity used in agricultural, pharmaceutical, food, textile, and other chemical markets. The global demand for FA is expected to be 820,000 metric tons in 2021 (Sesto, 2020). FA can be produced via electrochemical reduction (ER) or homogenous catalysis of CO₂ and H₂. Processing requirements range from 25 to 400 MJ/kg of FA produced (Rumayor et al., 2018). This would require less than one and up to three LWRs dedicated solely to the production of FA to meet global demand.

Selected hydrocarbon fuel route for TEA

As the focus of this study is synthetic transportation fuels, conversion pathways converting CO₂ to fungible hydrocarbon fuel were selected for detailed modeling and TEA. Production of syngas via co-electrolysis or RWGS result in the same overall chemical equation (Eq. 1); therefore, similar energy consumption. Co-electrolysis via SOEC was selected. As discussed, the possible range of syngas-to-fuel pathways is very extensive. From this extensive list, the possible range of technologies was down-selected to a methanol-based pathway, as methanol is a versatile chemical that can be further converted into fuels, and a wide range of chemicals and products.

The pathways selected for detailed analysis are shown in Fig. 7. The methanol pathway is based on established technology for methanol generation from syngas and production of olefins from methanol using the UOP's commercialized MTO process (Vora et al., 1998). Olefin oligomerization and hydrogenation technology are based on a PNNL-patented process (Lilga et al., 2016). The methanol pathway is considered to be at a high technology readiness level (TRL), as the syngas-to-methanol technology (using coal or NG) has been in use for decades and there are several industrial installations of the MTO process based on coal gasification, one being in China and one in Belgium (Gogate, 2019).

Techno-economic analysis methodology

The approach to developing conversion process techno-economics is similar to that employed in previous analyzes conducted for the DOE's Bioenergy Technologies Office (BETO) (Dutta et al., 2015; Jones et al., 2013; Jones and Zhu, 2009). Process flow diagrams and models are developed based on experimental research by PNNL, INL, and others, along with information from the literature and commercial vendors for mature and similar technologies. To assure consistency across all conversion pathways, BETO developed a set of economic assumptions that are used for bioenergy TEAs (DOE, 2016), which are also adapted for this work. An important aspect of these assumptions is that they reflect an "nth-plant" design, as described below.

Definition of Nth plant

A standard reference basis common to the conceptual design reports, known as the "nth" plant design, is used. These assumptions do not account for additional costs that would normally be incurred for a first-of-a-kind plant, including special financing, equipment redundancies, large contingencies, and longer startup times necessary for the first few plants. For nth-plant designs, it is assumed that the costs reflect a future time when the technology is mature, and several plants have already been built and are operating. The

Fig. 7 Selected syngas intermediate chemicals and pathways for fuel production through methanol.

Table 2 Nth-plant assumptions.

Assumption description	Assumed value
Internal rate of return (IRR)	10%
Plant financing debt/equity	60%/40% of total capital investment (TCI)
Plant life	30 Years
Income tax rate	21%
Interest rate for debt financing	8.0% Annually
Term for debt financing	10 Years
Working capital cost	5.0% of fixed capital investment (excluding land)
Depreciation schedule	7-Years MACRS ^a schedule
Construction period	3 Years (8% 1st year, 60% 2nd year, 32% 3rd year)
Plant salvage value	No value
Startup time	6 Months
Revenue and costs during startup	Revenue = 50% of normal Variable costs = 75% of normal Fixed costs = 100% of normal
On-stream factor	90% (7920 Operating hours per year)

^aModified accelerated cost recovery system.

specific assumptions are shown in **Table 2**. Note that tax incentives and other credits that may be applicable (e.g., credits under the Renewable Fuel Standard or cellulosic biofuels bonus depreciation) but are excluded from the analysis to represent plant economics independent of any government subsidies.

General cost estimation basis

All costs in this report are on a 2019 constant dollar basis. This is the current reference year that BETO uses to facilitate comparison of various conversion technologies. Capital costs are estimated from a variety of resources. The heat and material balances generated by the simulation software (AspenTech ASPEN-Plus; CHEMCAD v.7) are used to size the major pieces of equipment. Aspen Capital Cost Estimator (ACCE), information from published literature and vendors quotes are used to cost individual pieces of equipment. The original cost reflects the year of the cost quote or estimate, and the scale of the equipment. All capital costs are adjusted to an annualized 2019 basis using the Chemical Engineering magazine's published indices:

$$\text{Cost in 2019 \$} = \text{equipment cost in quote year} \times \left(\frac{2019 \text{ index} = 541.7}{\text{quote cost year index}} \right) \quad (2)$$

The scale is adjusted to match the appropriate scaling term (heat exchanger area for example) by using the following expression:

$$\text{Scaled equipment cost} = \text{cost at original scale} \times \left(\frac{\text{scale up capacity}}{\text{original capacity}} \right)^n \quad (3)$$

where n is the scale factor, typically, 0.6–0.7.

After equipment is scaled and adjusted to the common cost year, factors are applied to calculate the total capital investment. Individual installation factors calculated by ACCE are multiplied by equipment costs, unless installed costs are already available from vendors. The total direct cost is the sum of all the installed equipment costs, plus the costs for buildings, additional piping, and site development. Indirect costs are estimated as 60% of the total installed costs. Factors for the calculation of these additional direct and indirect costs are listed in **Table 3**. The sum of the direct and indirect costs is the fixed capital investment (FCI). The total capital investment is the fixed capital plus working capital and land costs.

Operating costs are estimated by using the results from the ASPEN-Plus heat and material balances and applying raw material and utility prices (given in individual pathway TEAs in following sections). Labor requirements and rates for the modeled synfuels plant are consistent with past TEAs performed for biomass-gasification-based fuel plants and are listed in **Table 4**. Note that labor needs associated with running the front-end SOEC portion of the plant as compared to a gasifier may be lower; therefore, these costs are likely conservative.

With the capital and operating costs, the MFSP is determined using a discounted cash flow rate of return analysis. The MFSP is the plant gate selling price of the fuel product that makes the net present value of the project equal to zero given the financial factors assumed (see **Table 2**).

Co-electrolysis of CO₂ and water to syngas

SOECs offer a unique method for converting CO₂ and steam into syngas. Co-electrolysis is preferred over separately electrolyzing steam and CO₂ because of reduced cell resistance (area-specific resistance, or ASR) and lower conversion of CO to C ([Stoots, 2010](#)).

Table 3 Cost factors for direct and indirect costs.

<i>Direct costs</i>	
<i>Item</i>	<i>% of Total installed cost (TIC)</i>
Buildings	4.0%
Site development	10.0%
Additional piping	4.5%
Total direct costs (TDC)	18.5%
Indirect costs	
Item	% of TDC
Prorated expenses	10%
Home office and construction fees	20%
Field expenses	10%
Project contingency	10%
Startup and permits	10%
Total indirect costs	60%
Working capital	5% of FCI
Land	HTL: 6 acres @ \$15,000/acre Upgrading: 6% of total purchased equipment cost

Fig. 8 details the process inclusive of the SOEC stack, heat exchangers, compressor, pump, and separators. In this process CO₂ and water enter the stack in vapor phase. Power supplied to the stack yield syngas and oxygen. Oxygen flows from the cathode to the anode and is removed by a sweep gas, typically air. Excess CO₂ and steam are separated from the stack output and reintroduced to the stack inlet.

SOEC design

Co-electrolysis of CO₂ and H₂O have been studied for the better part of a decade as method of producing syngas using the same technology as has been used over several decades for solid oxide fuel cell (SOFC)s. Rather than producing power, SOECs consume electrical energy (and sometimes heat) to convert CO₂ and H₂O in syngas.

Solid oxide electrolysis makes use of the same material and technology as solid oxide fuel cells. A single cell in an SOEC stack is comprised of an anode, cathode, and solid electrolyte. The cathode is typically constructed of nickel and yttria stabilized zirconium and the anode is a mixture of lanthanum, strontium, and manganese oxide. When power is supplied to the SOEC, steam and CO₂ are converted to H₂, CO, and O₂. This occurs via three reactions, namely the reverse water-gas shift and the co-electrolysis reactions:

A model was initially developed in ASPEN-Plus V10 to represent product stream compositions, and heat and power requirements for an SOEC stack. Inlet mole and conversion fractions were specified to produce the required ratio of H₂/CO of 2 in the syngas for the downstream methanol synthesis step. The model was developed to match results from experimentally validated SOEC models from the literature (O'Brien et al., 2009; Redissi and Bouallou, 2013) for approximately the same syngas ratios.

Fig. 8 Schematic of SOEC.

The model introduces CO₂/H₂O/H₂ at a molar ratio of 45:45:10 and a temperature of 300 °C to the stack. The mixture enters the stack whereupon RWGS occurs modeled as an equilibrium reactor labeled as LRWGS. A topping heater brings the mixture to the adiabatic stack operating temperature, in this case 800 °C. The stack is operated at a pressure of 0.1 Mpa, thermal neutral voltage of 1.34 V, and optimal current density and ASR of 0.4 A/cm² and 1.5 Ohm cm², respectively (O'Brien et al., 2009). Electrolysis occurs at thermo-neutral voltage in the stack modeled by a stoichiometric reactor (RSTOIC) using a fractional conversion from electrolysis reactions at 0.95 and 0.05 for H₂O and CO₂, respectively. RWGS again occurs at 800 °C. Although the Redissi model was validated experimentally, it is not representative of how a typical SOEC plant would operate. Nevertheless, the Redissi model served as a valuable first step in validating a working model for this study. Missing from the Redissi model was heat recuperation and recirculation of steam and CO₂ streams. Additionally, hydrogen is not a primary input to the stack as it is in the aforementioned model. As shown in Fig. 9, the model was updated to include heat recuperation (RHX1 and RHX2), greatly reducing the power input to the topping heater. The remaining electrical heaters were replaced with steam heat exchangers available from the LWR at 260–300 °C to super-heat the incoming gas streams (WX1 and WX2). Approximately 30% of the hydrogen was consumed in the RWGS; this was modeled by recirculating a portion of the hydrogen product to the inlet of the stack. The final syngas ratio was 2:1.

Fig. 9 ASPEN-Plus model with recirculation and heat recuperation.

SOEC cost estimation

Two different methods were used to estimate the cost of an SOEC system, one based on an extensive cost analysis of SOFCs, and the other based on an area-specific cost analysis of SOECs. The SOFC method only required the total electrical power required for the stack, whereas the other method required the number of cells required as calculated from Faradays Law. A detailed cost analysis was conducted for manufacturing, installation and operation of an SOFC for a nominal power output of 270-kW sized for ground-based distribution generation (Weimar et al., 2013). It found that electricity costs for a mass manufactured SOFC could be \$0.07/kWh based on a standard approach to manufacturing cells. A detailed study was conducted to understand the various steps required for manufacturing the units that included materials, equipment, and labor. Volumes were projected at 10,000 units/year. In addition, a sputtering approach for processing the units was considered and found to increase the performance of the stack and reduce capital costs by 33%. The cost study was based on 400-cm² cell area; however, the result was specific to power generation. Given the mole flow of monatomic oxygen from the cathode to the anode as given by the model, the number of cells can be determined from Faradays Law:

$$\Delta N_{\text{O}} = \frac{I_e}{2F}; \text{ where } I_e = iA_{\text{cell}}N_{\text{cells}}$$

Where the cell area is 250 cm² and the current density is 0.4 A/cm².

Using the sputtering method, the power-specific manufacturing and installation costs were found to be \$65/kW and \$182/kW, respectively. These costs are specific to the stack and housing costs and were scaled to provide an estimated installed cost for the SOEC in the modeled MTO-based fuel plant (278 MWe, see Section “Syngas to fuels via methanol-to-olefins process”) at \$68.8 M.

Table 5 shows a comparison of other SOEC cost estimates from the literature compared to Weimar’s method for the MTO-based model (Section “Syngas to fuels via methanol-to-olefins process”). Giglio et al. (2015) estimated the area-specific costs for a stack and its enclosure to be \$1500/m² of SOEC active area (i.e., the cell area). Using an assumed a cell size of around 225 cm² (O’Brien et al., 2009) to be acceptable given the available manufacturing techniques in 2009, and along with the current density of 0.4 A/cm² and monatomic oxygen flow across the cell from the model, the total cell area required is found to be 52,986 m². The total cost from this approach comes to \$79.5 M, for a difference of roughly 15% between the two approaches. Estimates from Buttler et al. (2015) and Anghilante et al. (2018) are \$93 M and \$61 M, respectively. The costs selected for this study (Weimar et al., 2013) is within the range of other literature values shown.

Syngas to fuels via methanol-to-olefins process

Design and modeling

The overall block flow diagram for the modeled distillate fuel production process through the MTO route is shown in Fig. 10. Syngas is first generated via co-electrolysis, as described in Section “SOEC design”. Raw syngas from the SOEC section is compressed to 420 psia. Entrained water is separated in knock-out pots prior to and between stages of compression and recycled back to the SOEC. Amine-based acid gas removal is then used to separate CO₂ from the syngas for recycle back to the SOEC. Removal of CO₂ also serves to reduce its concentration in the syngas feed to the downstream processes, thereby reducing equipment size and capital. Saturated steam at 374 °F is used to regenerate the amine solvent in a mass ratio of 2:1 for steam-to-CO₂ removed (Tan et al., 2016). Single-pass conversion of CO₂ is 29% and overall carbon efficiency to CO including recycle is 98.7%.

Syngas is then compressed to 925 psia, mixed with unreacted syngas, heated to 440 °F, and fed to the methanol reactor. Methanol synthesis occurs over a copper/zinc oxide/alumina catalyst. Process conditions for the methanol reactor are given in Table 6. Heat from the exothermic synthesis reaction is removed from the reactor via steam generation (Tan et al., 2016). Steam is used for downstream reboiler duties and for a portion of the steam needed in the CO₂ removal process. Single-pass conversion of CO is 34% and overall conversion with syngas recycle is 94%. Overall carbon efficiency of CO (and the low levels of CO₂ in syngas) to methanol is 93.2%.

Methanol is then preheated and fed to the MTO fluidized-bed reactor where ethylene, propylene, 1-butene, and 1-pentene are produced (Vora et al., 1998). Table 7 lists the assumed process conditions and conversion efficiencies. Some lights gases and coke are formed by side reactions; the coke is burned off periodically. The effluent mixture from the MTO reactor is cross exchanged to pre-heat the inlet gas and then quenched in a direct-contact, circulating-water spray tower to separate the non-condensable gases

Table 5 SOEC stack cost estimates from literature.

Source	Basis	Installed cost (stacks and enclosure)	MTO model (Section “Syngas to fuels via methanol-to-olefins process”) SOEC plant cost (2019\$; Scale 278 MWe)
Weimar 2013	Fuel cell power	\$247/kW	\$68.8 M
Giglio 2015	SOEC area	\$1500/m ²	\$86.7 M
Buttler 2015	SOEC area	\$1755/m ²	\$101.5 MM
Anghilante 2018	SOEC power	\$219.5/kW	\$61.5 M

Table 6 Process conditions for methanol synthesis reactor (exothermic).

Assumption	(Jones and Zhu, 2009; Phillips et al., 2011)
Temperature, F	440
Pressure, psia	920
H ₂ : CO ratio	2.0
CO ₂ concentration (mol%)	4%
Single-pass CO conversion	34%
Overall CO conversion	94%

Table 7 Process conditions for methanol-to-olefins (exothermic).

Assumption	Reference: Vora (1998) and Gelbein (2003)
Temperature, F	814
Pressure, psia	19.7
WHSV	1
Single-pass methanol conversion	99%
Overall methanol carbon efficiency to olefins	93.4%

from water generated by methanol dehydration. Residual methanol is stripped from the quench column wastewater and recycled to the MTO reactor. The overall conversion of methanol is 99.98% with an MTO carbon efficiency of 93.4%.

The olefin-rich gas mixture goes through various separation steps and catalytic reactors to produce longer-chained hydrocarbons in the diesel-boiling range in an oligomerization step (Lilga et al., 2016). Oligomerization reactor conditions and conversions are listed in Table 8. The separation steps include a lean-oil scrubber used to recover olefins and remove methane and other paraffin by-products to prevent their accumulation in recycle streams used to increase the product yield.

Lighter olefins are recycled to increase their carbon number to the desired range of 9–16. Two catalysts are used to produce dimers and trimers of the reactive olefins to increase the carbon number. In the first oligomerization reactor, operated at 570 °F

Table 8 Process conditions for oligomerization of olefins (exothermic).

Assumption	Dutta et al. (2015) and Tan et al. (2016)
Temperature, F (first stage)	320
Pressure, psia (first stage)	302
Temperature, F (second stage)	288
Pressure, psia (second stage)	140
Stage 1 C ₂ –C ₅ olefins C eff. to C ₆ + olefins	48%
Stage 2 C ₂ –C ₅ olefins C eff. to C ₆ + olefins	49%
Overall C ₂ –C ₅ olefins C eff. to C ₆ + olefins	98.6%

and 302 psia, an H-Beta Zeolite catalyst is used to produce dimers and trimers of smaller (C₂–C₄) olefins to C₆+ olefins. The overall oligomerization reaction is exothermic; therefore, no heat is needed to drive the reaction. The assumed net conversions of ethylene, propylene and butene are 75%, 82%, and 27%, respectively. The second reactor, operated at 326 °F and 140 psia, uses an Amberlyst catalyst to increase the yield of C₉–C₁₈ compounds. The net conversion assumed for C₄, C₅, C₆, C₇, C₈, and C₉ olefins to their dimers are 40%, 36%, 100%, 26%, 23%, and 3%, respectively.

Lighter olefins (in the C₄–C₉ range) are recovered and recycled as part of the lean-oil scrubber feed, and the heavier olefins are hydrogenated using separately purchased hydrogen over a Pd-on-alumina hydrogenation catalyst operating at 750 °F and 130 psia. The H₂ partial pressure is maintained at about 70% of total pressure to minimize coking and to completely hydrogenate all double bonds in the feed. The excess hydrogen is separated from the diesel product after condensation and knock-out pots. It is recycled to the reactor operating pressure using a pressure booster. The hydrogenated product is distilled into gasoline (9%) and diesel (91%) blend stocks in a final distillation column. Overall carbon efficiency of olefins to fuel product is 98.5%.

Performance and economic results

Fig. 11 shows the resulting power and heat inputs and outputs for the modeled MTO process. About 92% of the power demand is for the co-electrolysis unit, with the remainder consumed for gas compressors and pumps throughout the plant. Steam is used for heating of the feed CO₂ and water to the SOEC system, for recovery of the amine solvent in the CO₂ recovery process, and for column reboilers and heating of various process streams. About 84% of the steam requirement for the integrated plant is for amine solvent recovery (shown as CO₂ Sep block below). Heat from the methanol reactor (syngas to MeOH block below) is used to produce a portion of the steam requirement, with the balance supplied by saturated steam (536 °F) from the LWR. The net power

**Fig. 11** Electrical and thermal inputs/outputs for the synfuels via MTO process using nuclear heat.

and heat requirements for the fuel plant are 326 MWe and 133 MWt. Electrical and thermal energy usage for syngas production for the modeled SOEC portion of the plant is 3.2 MWe/lb. syngas and 19.4 MWt/lb. syngas, respectively, for a H₂:CO ratio of 2.1. Note that this is only the energy usage for producing raw syngas and does not include steam used to recover amine solvent for separation of CO₂. All reactors downstream of syngas production and CO₂ separation are exothermic; therefore, no steam/heat is needed to drive these steps. For the syngas-to-methanol step, steam is generated on the shell side of the methanol reactor, capturing 31 MW of thermal energy. For the methanol-to-olefins step, 8.5 MWt of steam is generated from heat contained in the flue gas from the MTO reactor catalyst regenerator and 3.3-MWt steam is used to heat the feed stream and for the methanol recycle recovery column reboiler. For the oligomerization step, the heat generated is relatively low quality (<450 °F) and is not included in the overall thermal heat generation; however, it can be used for boiler water preheating. Distillation towers for separation of oligomers use 5.3 MWt of steam in reboilers. For the hydrotreating step, 6.3 MWt of steam is generated from the hot reactor effluent and 0.6 MWt of steam is used for reboiler heat in the diesel/naphtha fractionation column.

Table 9 lists the raw material, waste disposal and utility costs assumed for estimating variable operating costs for the fuel production plant. [Boardman et al. \(2019\)](#) estimated the levelized cost (including capital and operating expenses) of CO₂ delivered to a hybrid LWR-methanol plant scenario including capture from an ethanol plant, compression, storage, and transportation via pipeline to the nuclear power plant. They determined a range of \$14.6 to 38.3/t for a 530 t/day capacity methanol plant. The mean of this range (\$33.3/t) was used in this study and sensitivity analysis was conducted around this assumption. For comparison, the breakeven CO₂ sales price estimated for capture from fossil energy plants ranges from \$44/t to \$119/t ([James et al., 2019](#)). A range of \$0 to 120/t CO₂ cost was investigated in the sensitivity analysis. Although clean O₂ could potentially be a co-product of the process, to be conservative, no O₂ credit is included in the analysis.

Table 10 gives the major performance and economic results for the synfuel plant. Also presented for comparison is the biomass case, where gasification of woody feedstock is used on the front end instead of co-electrolysis. Woody feedstock cost is assumed to be \$63.23/dry ton ([Hartley et al., 2018](#)). Feedstock CO₂ and water for the SOEC are 1549 t/day and 331,369 gal/day, respectively. For perspective, this is about 1.75 times the daily CO₂ produced from a typical corn ethanol plant (100 million gallon/year) and about half the capacity of an Olympic-sized swimming pool, respectively. Fuel generation is about 2900 barrel/day (BPD) of diesel and 295 BPD of naphtha (motor gasoline blendstock). The U.S. demand for diesel and gasoline in 2019 was 3.3 million BPD and 9.3 million BPD, respectively ([EIA, 2020a](#)). Energy efficiency for the co-electrolysis process is similar to the gasification case, but overall carbon efficiency is much higher due to the high selectivity of the electrolysis reactions. Feedstock cost is higher for the biomass case due to the lower carbon efficiency as compared to the co-electrolysis case. Capital costs for the syngas generation are higher for the co-electrolysis case due to the assumed cost of the SOEC stacks. However, syngas cleanup and methanol production costs are lower due to a cleaner and lower total flow of gas (fewer light ends and CO₂ than from gasification) through the compression system and reactor than results from biomass gasification. The fuel production cost breakdown is given on the bottom half of **Table 10** and illustrated in **Fig. 12**. The MFSP for the SOEC case is \$4.45/gal, with electricity and steam cost making up about half of the total production cost. Optimistic and conservative cases using the lower and upper bounds respectively for estimated electricity and steam price from an LWR (\$0.02/kWh with \$2.49/1000 lb1000lb and \$0.04/kWh with \$4.70/1000 lb1000lb steam, respectively) are included for comparison. Most of the steam requirement is for removal of CO₂ from the syngas (recovery of amine solvent). In the biomass gasification case, extra steam is generated from heat recovered from the char combustor, which supplies all heat needs for the plant as well as onsite generation of power. In the SOEC case, steam must be supplied from the LWR.

Economic studies from the literature for synthetic fuels production yield a wide price range. This is to be expected with the highly variable processes and technical and economic assumptions that are possible. One of the most established technologies for converting syngas to hydrocarbon fuel is via the FT route. Several pilot and demonstration tests using co-electrolysis-based syngas with FT synthesis from syngas to fuels were conducted between 2014 and 2022 in Europe (Dieterich et al., 2020). Several groups have conducted TEAs for FT fuels via electrolysis of CO₂. Li et al. (2016) reported a range of \$3.80 to 9.20/gal with a range of well-to-gate energy efficiency of 41–65%. Becker et al. (2012) found a range of \$4.4 to 15/GGE (gasoline-gallon equivalent) for electricity price range of \$0.02 to 0.14/kWh and plant capacity range of 90–40% and reported an overall efficiency of 51% (LHV). In a study by Fu et al. (2010), production cost ranged from \$2.50 to 6.79/gal with an electricity price of \$22–88 MWh. Cost results from this analysis lie within the general cost range of FT fuels found in the literature.

It is evident that the MFSP for the low-carbon fuel from this pathway fuel is higher than current market petroleum fuel prices (Fig. 13). However, possible carbon credits through government incentives or mandates are not considered in these results and could be substantial if put into place in the future. For example, credits like those granted under the Environmental Protection Agency (EPA) Renewable Fuel Standard (RFS) for biofuels may be a good first approximation for future incentives associated with CO₂-based fuels. State programs such as California's low-carbon fuel standard (LCFS) could bring additional value incentives. Renewable identification number (RIN) credits for advanced biofuel, defined as fuel with associated lifecycle greenhouse gas (GHG) emissions that is 60% lower than the petroleum baseline (e.g., gasoline and diesel), was valued in the range of \$1.01 to 2.74 per gallon over the 2018–19 time period (Fig. 14, (EPA, 2020)). Lifecycle GHG emissions for the MTO-based fuel from co-electrolysis are estimated at 13.8 g CO₂-e/MJ as shown in Table 11. This represents an 85% reduction in GHGs compared to petroleum diesel (91.8 g CO₂-e/MJ, GREET, 2019). Note that this is a relatively high-level estimate that includes emissions associated with feedstock production/preparation (compression of CO₂ feed at the ethanol plant for CO₂ and woody biomass collection and preparation for

Fig. 12 Fuel production cost breakdown for renewable fuel blendstock via co-electrolysis and biomass gasification and the MTO route for the conversion of the syngas to synfuels.

Fig. 13 Petroleum fuel price history (EIA, 2020b).

the gasification case), electricity (nuclear power for the co-electrolysis case and grid power for the biomass case) and hydrogen used for hydrotreating olefins into final fuel blendstock.

Sensitivity analysis (Fig. 15) investigating variable CO₂ cost, CO₂ credits, and electricity price shows that with optimal CO₂ and electricity prices and inclusion of carbon credits through incentives or mandates could make this process more cost competitive with petroleum fuels. With a hypothetical carbon tax of \$100/t CO₂ the MFSP is reduced to ~\$3.75/gal. An RFS credit would further aid in competitiveness of fuels produced via this route. Carbon sequestered into fuel minus CO₂ emitted in process off gas combustion and embodied GHGs for H₂ requirement for hydrotreating of the final fuel was estimated. The carbon credit reduces MFSP by

Fig. 14 Price for renewable fuel credits during 2018–19 (EPA, 2020).

approximately \$0.86/gal, somewhat less than the average 2018/2019 D3 advanced biofuel RIN price of \$1.88. This analysis indicates that fuel from this pathway could be more competitive with petroleum prices with a combination of lower electricity price, lower CO₂ price, and qualifying carbon credits. If a D3 RIN-type price could be applied, competitiveness could be further improved.

Also, there are innovative cryogenic carbon capture (CCC) processes that could have significant impact on the viability of an LWR/synfuels plant using methanol as intermediate. Further, the refrigerant used in the CCC process could be produced using LWR energy. The synergies of the LWR with the CCC process and techno-economic modeling of the CCC process will be explored in detail in future studies.

Conclusions and future directions

This article gives a general overview of the many possible pathways to produce sustainable hydrocarbon fuels and chemicals from CO₂ and H₂ and presented detailed process model and TEA for one example of power-to-fuels using steam and electricity from an LWR. Using the base case assumptions of \$33.3/t CO₂ cost and \$30/MWh electricity cost, the modeled MFSP for the methanol-based route to fuel is estimated to be \$4.45/gal for a fuel production plant of 3194 BPD capacity. Production costs for the co-electrolysis routes using these above assumptions leads to a cost about 40% higher than using wood gasification for syngas production, primarily due to electricity usage and steam usage for co-electrolysis and CO₂ separation. The assumptions used in the base case are conservative and do not account for improving technologies in the areas of CCC. Sensitivity analysis shows that a combination of lower electricity and steam price (\$20/MWh and \$2.49/1000 lb. steam), low CO₂ price (\$15–50/t), and inclusion of carbon credit of a \$100/t can make the process more competitive with petroleum fuels. GHG analysis indicates that the fuels have 85% less GHG emissions than petroleum fuels (diesel) and could conceivably qualify for the highest RIN credit if approved by the EPA. This, along with additional state incentives could bring an even higher potential credit for the fuel.

A recent report studied the framework of options that can incentivize nuclear power plant operations by providing credits for the low-carbon grid power and non-electric products that may be produced from nuclear power, similar to REC. Some conclusions from this report are highlighted below as they apply to synthetic fuel produced by coupling with low-carbon nuclear energy.

Other reports completed by the DOE LWRS program have highlighted the vast and diverse markets for non-electric products that can be produced using nuclear energy (Knighton, 2020; Hu et al., 2019; Frick et al., 2019). The current chapter has supplemented these studies by providing a first look into two possible pathways for producing synthetic transportation fuels by coupling with low-carbon nuclear energy.

Retiring nuclear plants and not valuing this low-carbon energy with the commensurate credits given to renewable energy may lead to drastic increases in carbon emissions (from substitute baseload plants such as NGCC) at a time when decreases in carbon emissions are being sought, which would be contrary to the goals of decarbonization.

Important points to consider related to possible future low-carbon/zero emissions credit legislation:

- The retention of nuclear power generation is critical to achieving federal and states' decarbonization goals across multiple energy sectors.
- Producing hydrogen and other products such as synthetic fuels from nuclear power, especially at low demand periods, increases the capacity utilization factor of NPPs, which can improve the economics of their operation.
- The contribution of nuclear power to zero-carbon power markets can be extended further to serve other energy sectors such as transportation, as well as building and industrial heat demand, thus contributing to the goals of decarbonization across multiple energy sectors.

Glossary

Ammonium nitrate A chemical compound with the chemical formula NH_4NO_3 . It is a white crystalline solid consisting of ions of ammonium and nitrate. It is highly soluble in water and hygroscopic as a solid, although it does not form hydrates. It is predominantly used in agriculture as a high-nitrogen fertilizer. Global production was estimated at 21.6 million t in 2017.

Haber-Bosch process An artificial nitrogen fixation process and is the main industrial procedure for the production of ammonia today. It is named after its inventors, the German chemists Fritz Haber and Carl Bosch, who developed it in the first decade of the 20th century.

Urea A common form of fertilizer produced by combining ammonia with carbon dioxide which can be formulated into a solid or solution for agriculture application.

Introduction

Ammonia is the basic building block of the world nitrogen industry; consumption of ammonia for nitrogen fertilizer accounts for more than 93% of the world ammonia market. Nitrogen fertilizers are the most widely used fertilizers in the world, accounting for close to 73% of all fertilizers. With the exception of China, where much of the ammonia is produced from coal gasification, most of the world's ammonia is produced from natural gas via steam reforming. From 2011 to 2020, world apparent consumption of ammonia increased at about 2% per year (Food and Agriculture Organization of the United Nations (FAO), 2019; ICIS, 2017). Ammonia capacity is increasing primarily in areas where the availability and cost of natural gas are lower, in particular the United States and the Middle East. The global ammonia supply/demand balance is expected to move toward a surplus, as future capacity additions will continue to outpace consumption, leading to declining utilization rates.

The major method for commercial production of anhydrous ammonia is a modified Haber-Bosch process from natural gas via steam reforming (Pattabathula and Richardson, 2016).

The process converts atmospheric nitrogen (N_2) to ammonia (NH_3) by a reaction with hydrogen (H_2) using a metal catalyst under high temperatures and pressures:

This process was first demonstrated in 1909 and was commercially developed in 1913 by BASF in Germany with a capacity of 30 Mt. d^{-1} . During the past 60 years, ammonia process technology has improved drastically. Plant layouts evolved from multi-train designs, often with different numbers of trains in the front end and synthesis loop, to single-train designs. Synthesis gas preparation in the front end of the plant increased from atmospheric pressure to 30–50 bar_g pressure. Capacities increased from 100 t d^{-1} to as much as 3300 t d^{-1} in a single train. Energy efficiencies have improved as well—from consumption above 60 GJ t^{-1} of ammonia in coal-based plants to 40–50 GJ t^{-1} in the first natural gas based plants to 30–40 GJ t^{-1} in single-train plants. Modern plants have added heat recovery by steam production at pressures as high as 125 bar_g in both the syngas preparation section and the synthesis loop.

Nuclear energy can be used to support ammonia production and its associated fertilizer products in both a direct and indirect direct manner. Although ammonia synthesis is exothermic and gives up some useful heat, hydrogen production by natural gas reforming at the start of the process train is highly endothermic and requires extra, high temperature heat. This is provided by burning about 25–35% of the natural gas feed. Even after heat integration, the best plants still emit a significant amount of CO_2 . With some simple modifications to the natural gas reformers, nuclear-generated thermal energy can replace all of the natural gas that is combusted.

Alternatively, hydrogen production by electrolysis or water or steam and separation of nitrogen from air can be performed separately and stored for use by the Haber-Bosch ammonia synthesis reactor. Hydrogen, nitrogen, and ammonia production need not be synchronously operated and can be powered by a nuclear plant. This form of indirect coupling with a nuclear plant has several advantages, including total elimination of GHG emissions. It also provides flexibility in allowing the nuclear power plant to provide peak power to the electricity grid when the revenue generation by participating in the capacity market is greater than the cost of hydrogen and nitrogen storage. In this manner the Haber-Bosch process can be operated at steady state.

This section summarizes a comprehensive analysis completed by Idaho National Laboratory under the United States Department of Energy (US DOE) Next Generation Nuclear Plant Program (Wood, 2010). In this study, the possibility of integrating a High Temperature Gas-Cooled Reactor (HTGR) with conventional steam methane reforming and coal-gasification ammonia production plants were evaluated. The principles developed in the research activity are widely applicable to other advanced nuclear reactor designs. At a minimum, hydrogen that is produced by coupling a nuclear plant to a water-splitting electrolysis plant can have a large impact on ammonia and ammonia-derivative products and fertilizers, such as urea, nitric acid, and ammonium nitrate.

Conventional ammonia production plants

Producing ammonia from natural gas and coal are fundamentally different. Natural gas is hydrogen rich with a carbon-to-hydrogen ratio of 1:4. Coal is hydrogen limited with a carbon-to-hydrogen ratio of approximately 1:0.8. Coal requires significant capital to gasify and to clean up the resulting syngas of CO and H₂. CO is then used to produce additional H₂ via the water-gas shift reaction:

Excess heat is generated in the coal-based case due to carbon rejection (as CO₂).

Fig. 1 shows a representative block flow diagram for a conventional natural gas-to-ammonia plant and associated products. The overall process includes unit operations for natural gas reforming, syngas cleaning and conditioning, CO₂ compression, ammonia synthesis, nitric acid synthesis, ammonium nitrate synthesis, urea synthesis, power production, cooling towers, and water treatment.

Fig. 1 Block flow diagram for the conventional natural gas-to-ammonia process. Next Generation Nuclear Plant Wood RA (2010) *Nuclear-Integrated Ammonia Production Analysis*. Technical Evaluation Study-666. Project 23843.

Syngas feeding the ammonia synthesis unit is adjusted to achieve the H_2/N_2 molar ratio 3.0. Incoming feed gas is compressed to 3000 psi. Unreacted recycle gas is mixed with the fresh feed gas and preheated by cross exchanging with hot reactor effluent gases. Equilibrium conversion is assumed in the ammonia converters by the following simple molecular balance of Eq. (1).

Two-step reforming consisting of primary steam reforming followed by secondary autothermal reforming was selected for syngas generation. Air is used as the oxidant in the autothermal reforming step, as this provides nitrogen to the process for downstream ammonia synthesis (Eggerman, 2010). By carefully controlling process parameters, such as the steam-to-carbon inlet molar ratio, primary reformer temperature, amount of preheat to the secondary reformer, and secondary reformer temperature, a syngas containing the appropriate H_2/N_2 ratio for ammonia synthesis can be produced. Additionally, if the steam-to-carbon ratio is set high enough, additional water will not be required prior to downstream shift conversion. For this case, key parameters were set as follows:

Preformer steam-to-carbon ratio	3.30
Primary reformer exit temperature	790 °C
Autothermal reformer outlet temperature	950 °C

Effluent from the first ammonia converter is cooled by cross exchange with the reactor influent, followed by cooling in a steam generator. Additional steam is generated from the hot syngas downstream of the second and third ammonia conversion stages. Final cooling of the third stage effluent gas is accomplished using cooling water and recuperation with the cool recycle gas stream. Ammonia product is recovered in an ammonia separator. Effluent gas from this separator is further cooled using refrigeration. Additional ammonia is recovered in a second separator downstream of the refrigeration unit. Effluent gas from the second separator is recycled to the ammonia converters. Before entering the ammonia converters, the recycle gas is recompressed using a boost compressor and mixed with fresh syngas.

A mono-pressure process is used for nitric acid synthesis due to capital cost advantages over a dual-pressure process. Cold ammonia is first preheated prior to mixing with compressed air. The ammonia-air mixture is reacted in an ammonia converter to produce N_2 , NO, and H_2O . Due to the exothermic nature of the reactions, an exit temperature of 925 °C is reached. Heat recuperation and steam generation are implemented downstream of the converter. As the gas cools, additional reaction with oxygen takes place to produce NO_2 , N_2O_4 , and finally HNO_3 . Aqueous nitric acid is separated from the product stream while gaseous products are routed to an absorber to increase the yield of acid. A bleacher is included to further enhance reaction of NO with oxygen to improve acid yield. Unreacted gas exiting the absorber is routed to a selective catalytic reduction unit for NO_x abatement prior to release to the atmosphere. This tailgas is also run through an expander, which significantly reduces the net electrical load required for air compression.

Ammonium nitrate is produced by combining ammonia with nitric acid after preheating the feed to a neutralizer where the following reaction occurs (Speight, 2002):

Feeds to the process are controlled to maintain a pH of 1.5 in the neutralizer. The neutralizer products are then separated under slight negative pressure to remove excess water from the ammonium nitrate solution. Ninety-five percent of the solution is recycled back to the neutralizer, while 5% is withdrawn and further concentrated in a two-stage evaporator. Following evaporation, the concentrated ammonium nitrate solution is solidified using a prill tower. Process recycle and heat recuperation minimize energy input requirements.

Urea is produced by reacting ammonia with CO_2 to form ammonium carbamate, which simultaneously dehydrates to urea to form liquid product (Mavrovic et al., 2000):

It is convenient to separate the CO_2 produced by the combustion of natural gas or the coal gasifier outgas. Liquid urea product is concentrated using evaporation under vacuum conditions. The concentrated urea solution is then solidified using a fluidized bed granulator.

Fig. 2 shows the block flow diagram for a conventional coal-to-ammonia plant with production of derivatives. Major differences relative to a gas-to-ammonia plant are the air separation, coal milling and drying, coal gasification, syngas cleaning and conditioning, sulfur recovery, and CO_2 purification/compression unit operations. These units are not insignificant. The capital cost and maintenance of coal (or biomass) gasifier, and syngas cleanup is higher than a steam methane reforming process unit. Sulfur (mostly in the form of H_2S) must be separated from the syngas stream and recovered in a Claus sulfur recovery plant (Breckenridge et al., 2000; Burr and Lyddon, 2008). Oxygen is produced via a standard cryogenic Linde-type air separation unit (ASU) that utilizes two distillation columns and extensive heat exchange in a cold box. The oxygen product is used for gasification. An O_2 purity of 99.5% is specified, although a 95% O_2 purity plant would also be suitable for this application. Oxygen demand for gasification drives the size of the ASU; hence, in addition to the primary nitrogen demand for ammonia synthesis, excess nitrogen is also available for other plant uses, such as coal drying and transport.

Fig. 2 Block flow diagram for the conventional coal-to-ammonia process. Next Generation Nuclear Plant Wood RA (2010) *Nuclear-Integrated Ammonia Production Analysis*. Technical Evaluation Study-666. Project 23843.

Nuclear-integration with ammonia plants

Fig. 3 shows the block flow diagram for the nuclear-integrated natural gas-to-ammonia case. The proposed process includes the same unit operations as the conventional natural gas process except nuclear heat is used in the primary reformer rather than burning natural gas. Nuclear heat is also used to preheat all streams entering the primary reformer. Although nuclear heat could be used by the urea synthesis and water treatment plants, sufficient low-temperature heat is produced elsewhere in the plant to meet these requirements. Because higher temperature heat is desired for steam reforming of natural gas, this configuration assumes the use of an intermediate heat exchanger (IHX) to provide 700 °C helium gas as the heat transfer fluid to the reformer. This allows the conventional tubular reforming reactors to be adapted without significant modification to the reactor. Additionally, an electrically assisted compander in the nitric acid block allows pressure exergy to be conserved.

Fig. 4 shows the block flow diagram for the nuclear-integrated coal-to-ammonia case. As this diagram shows, a need for high-temperature heat (> 300 °C) integration was not identified. Additionally, modeling results for the conventional coal-to-ammonia case indicate that heat for coal drying, water treatment, and urea synthesis can be supplied by existing unit operations in the conventional configuration. Hence, electricity is the best integration option for this flow sheet. Because light water reactors could supply this need, there is no driving reason to integrate this flow sheet with that for advanced nuclear reactors.

Fossil fuel-free ammonia plants

The advent of water-splitting electrolysis is recognized an approach to producing ammonia without the production of syngas and hydrogen from fossil-fuel sources. It only becomes necessary to produce a stream of nitrogen to produce the ammonia. This can be accomplished with an air separation unit (ASU) equivalent in operation, but smaller than the ASU featured in the coal gasification process. Alternatively, nitrogen at sufficient purity can be generated by burning hydrogen and condensing the vapor byproduct, but this option was proven to be significantly more energy intensive and costly than obtaining nitrogen with an ASU. In this section, high temperature steam electrolysis (HTSE) is considered favorable to low temperature electrolysis given the greater thermodynamic synergy with nuclear reactors.

Fig. 3 Block flow diagram for the nuclear-integrated natural gas-to-ammonia process. Source: Next Generation Nuclear Plant Wood RA (2010) *Nuclear-Integrated Ammonia Production Analysis*. Technical Evaluation Study-666. Project 23843.

Fig. 5 shows the block flow diagram for a high temperature steam electrolysis (HTSE) hydrogen-to-ammonia case. Hydrogen for ammonia synthesis is produced by HTSE. Nuclear HTGRs supply heat and power for the electrolysis units as well as power for the ASU. An opportunity was identified to use heat from the natural gas burner as topping heat for the electrolysis unit. As HTGR technology matures and reactor outlet temperatures increase, the nuclear reactors may be able to supply electrolysis topping heat. However, because of the upper limit of 700 °C deliverable heat from the currently proven class of HTGRs, topping heat from the burner to the electrolyzers is an attractive means of increasing electrolyzer efficiency and leads to a small penalty on the overall carbon footprint.

Urea production requires CO₂ as a feed to the process. For this case, a CO₂ supply is not readily available and must be produced to support urea manufacture; hence, natural gas is burned with oxygen provided from the ASU to produce the required CO₂. If a source of CO₂ is available from a carbon capture plant, or a biological ethanol fermentation plant, then the life-cycle carbon footprint will be lower.

Process modeling results

Based on the results for the conventional coal-to-ammonia case, a need for high-temperature (> 300 °C) heat integration was not identified for the coal-fed case. In addition, because light water reactors can supply power in this scenario, a strong need for integration with advanced nuclear reactors is not apparent. Hence, modeling of a nuclear-integrated coal-to-ammonia case was not pursued by Wood (2010). Other gasification technologies (hydrogasification) could be considered, and these technologies may be more complementary for high temperature nuclear reactors.

Analysis of the conventional natural-gas-to-ammonia case indicates a strong potential heat integration opportunity for a HTGR. In the conventional case, 22.7% of the natural gas feed to the process is burned to provide heat in the primary reformer. The operating temperature in the primary reformer is 790 °C, which is somewhat higher than the assumed 700 °C temperature that can be supplied by the current generation HTGR. Analysis seems to indicate, however, that primary reforming can be accomplished in two

Fig. 4 Block flow diagram for the nuclear-integrated coal-to-ammonia process. Next Generation Nuclear Plant Wood RA (2010) *Nuclear-Integrated Ammonia Production Analysis*. Technical Evaluation Study-666. Project 23843.

stages—the first using nuclear heat at 690 °C, followed by a second stage reformer fueled entirely by purge gas that operates at a somewhat higher temperature.

Fig. 6 graphically presents a high-level material and energy balance summary for each case (Nelson, 2010). Results for the nuclear-integrated natural gas-to-ammonia case look promising. One 450 MW_t HTGR would be required to support this configuration. The split of heat to power required from the nuclear plant is 42%/58%. By substituting nuclear heat for natural gas combustion in the primary reformer, natural gas consumption can be reduced by 18%. In addition, CO₂ emissions can be reduced by 70%.

Although not shown previously, a case for producing nitrogen by burning hydrogen to deplete the oxygen in air was also evaluated by Wood (2010). The block flow diagram for this case was not presented because the cost of capital was significantly higher. This is reflected in the number of HTGR units required to support such an option.

Results for the HTSE hydrogen/ASU case look promising. CO₂ emissions are cut to very low levels, and the need to sequester carbon is eliminated. In addition, natural gas consumption is reduced to only the amount required to supply carbon for urea production. This option requires roughly four 600 MW_t HTGRs to fulfill the total electrical and heat duties required. This leaves surplus electricity for sale to the grid; alternately, the size of the hydrogen plant can be scaled up to match the energy output of all four HTGE units.

Economic comparison

The economic viability of the ammonia processes was assessed by Wood (2010) using standard economic evaluation methods. The economics were evaluated for the conventional and nuclear-integrated options described in the previous sections. The total capital investment based on the total equipment costs, annual revenues, and annual manufacturing costs were first calculated for the cases. For purposes of comparing the various options, the cost of producing urea is provided relative to the price of natural gas and the cost of the capital and operating costs of the plant.

The cost of one 600 MW_t HTGR in 2010 was estimated to be 2000 \$ kW⁻¹ installed (Nelson, 2007). Projections for an nth-of-a-kind target were estimated to drop to \$1400 \$ kW⁻¹ (Wood, 2010). Over the past decade, several reactor developers have

Green shading indicates nuclear assisted options that are closely competitive with conventional urea plants and recent market prices.

proposed concepts for advanced reactors, including new designs for the HTGR. Molten-salt reactors that operate in a comparable temperature regime are also being developed by private industry. Hence, for comparison, three levels of capital costs associated with the attendant nuclear plant are included here; 2000, 1400, and 700 (\$ kW⁻¹) installed capacity.

The costs of urea production based on a detailed discounted cash flow analysis are tabulated in **Table 1** for the following assumptions:

- Debt to equity ratios equal to 80%/20%, with a discount rate on the debt of 8%, and an internal rate of return on investment (IRR) of 12% on the equity.
- 15-year debt payoff and project life of 30 years.
- Combined (effective) tax rate of 38.9%.
- Inflation rate of 2.5% for the life of the project.
- Operating on-line capacity of 92%.

Natural gas prices beginning at the start of the project (prior to inflation) were varied to account for the large fluctuations seen in the market. The average cost of industrial market prices of natural gas for the life of the project are low (4.7 \$ GJ⁻¹), (mid-term 6.50 \$ GJ⁻¹), and high (12.00 \$ GJ⁻¹).

Based on the results for the economic evaluation of Wood (2010), integration of nuclear heat into a gas-to-ammonia process appears to become competitive once the cost of the HTGR reaches the target of \$1400 (\$ kW⁻¹) installed thermal capital cost. Although the HTGR/HTSE integrated flowsheets offer even greater benefits in terms of reduced natural gas consumption and carbon emissions, this case only is only shown to be competitive under the following conditions: (1) the capital costs of the nuclear reactor are reduced below 700 (\$ kW⁻¹) installed thermal capital costs, (2) the average price of natural gas prices are relatively high (viz., > 12.00 \$ GJ⁻¹) and (3) credits for avoiding CO₂ emissions are high (here above 200 \$ t⁻¹).

Conclusions

Ammonia production, including its attendant derivative fertilizers (urea and ammonium nitrate), is one of the largest industries worldwide. This Chapter Section shows nuclear energy integration with ammonia production is technically feasible and economically viable. High temperature reactor heat can be substituted for the heat used to reform natural gas. When combined with the direct use of electricity for the compression duties and pressure exergy conservation with application of companders, GHG emissions of a conventional process can be reduced to near zero. For the assumptions invoked in reference study, indirect integration of hydrogen and nitrogen with a Haber-Bosch process is becomes competitive when the cost of the nuclear reactor falls to around 700 \$ kW⁻¹ and there is a carbon emissions offset of around 200 \$ t⁻¹.

Glossary

Computational fluid dynamics (CFD) Pertaining to computer-based, quantitative description of a flow system.

Concentrate The product of ore dressing operations in which unwanted minerals are largely removed from the ores collected from mining operations before further treatment to obtain products. Iron ore concentrate typically contains 0.02–0.06 mm iron oxide particles.

Flash reaction Reaction of fine solid particles with a gas in a particle-gas flow stream, usually at a high temperature.

Residence time The average amount of time that a portion of material spends in a reactor while flowing through it.

Introduction

Ironmaking is an energy-intensive process and is thus one of the largest emitters of carbon dioxide. The conventional ironmaking technology is asymptotically approaching its practical efficiency limits. This means that even if we invest in the most modern facilities, only marginal energy and emissions reductions would be achieved. Therefore, the steel industry must develop a new technology to produce iron. An ideal process would replace the blast furnace and coke oven to reduce energy requirements and greenhouse gas emissions.

This article describes the development of a novel Flash Ironmaking Technology, conceived by (Sohn, 2007) that is based on the gaseous reduction of iron oxide concentrates in a flash reactor. It takes advantage of the large specific area of fine particles of iron ore concentrate. The development of the novel process also contains two of the most critical components for the future of metal production in general and steelmaking in particular, i.e. CO₂ emissions and energy saving. The steel industry contributes around 6–7% of the total anthropogenic emissions of CO₂ (Tacke and Steffen, 2004). The technology described here has the potential to significantly reduce energy consumption by 57% and lower carbon dioxide emissions in the ironmaking step down to a negligible level of just 4% of the level from the blast furnace process, when hydrogen is used as the fuel/reductant and that hydrogen is made by non-emitting processes, such as nuclear-driven electrolysis.

More than 90% of iron is currently produced by the blast furnace process, while the balance is produced by the direct reduction processes (IISI, 2007). The blast furnace process requires the feed in the form of sinters or pellets and coke made from high-grade coking coal. These two steps consume much energy and are problematic from the environmental perspective.

Previously developed processes for the gaseous reduction of iron oxide can be grouped into two broad types: shaft furnaces (Midrex and Energiron; Lockwood Greene Technologies, 2000) and fluidized-bed reactors (FINMET and the earlier FIOR (Brent et al., 1999), CIRCORED (Husain et al., 1999), and SPIREX (Macauley, 1997)). Most of these processes, however, are not sufficiently intensive to replace the blast furnace because they cannot be operated at high temperatures due to the sticking and fusion of particles. The shaft furnace processes, which currently are the dominant types for alternate ironmaking, require pelletization of iron oxide concentrate accompanied by additional cost and environmental problems, and also frequently suffer from pellet disintegration and sticking problems.

Therefore, a new technology named the Flash Ironmaking Technology (FIT) has been developed at the University of Utah for producing iron directly from fine concentrates by a flash smelting process. This is accomplished by adopting a reductant gas such as natural gas, hydrogen, syngas, or a combination thereof, while bypassing pelletization/sintering and cokemaking required

in typical ironmaking processes (Sohn, 2007; Sohn and Choi, 2010; Sohn et al., 2009a,b). Unlike other gas-based alternative ironmaking processes based on shaft furnaces or fluidized-bed reactors, the FIT will not suffer from the problems that plague other processes when operated at high temperatures, mainly from the sticking and fusion of particles. Low-temperature disintegration problems encountered in the processes using pellets are also eliminated. The availability of large quantities of iron ore concentrate produced in the United States and elsewhere will also be a backbone for this technology. Up to 70% of the US iron production is based on taconite concentrate (50–55 million tons/year) (USGS, 2007) with particle sizes of $< 100 \mu\text{m}$.

Below, we will present the description of the novel ironmaking process and the results of the operation of a pilot plant together with work on flow sheet development, process simulation, and economic feasibility analysis.

Description of the flash ironmaking technology (FIT)

A schematic diagram of the Flash Ironmaking process is given in Fig. 1. Hydrogen or natural gas is partially oxidized with tonnage oxygen through a burner on top of the flash reactor to generate a reducing gas stream at 1600–1900 K. Iron ore concentrate is injected near the burner and reduced in the reactor. Although this figure shows the operation of the process in which the reduced iron is collected as a molten bath for direct steelmaking in the unit, iron may also be collected as solid product to be used in steelmaking furnaces (Sohn, 2007).

For annual production of 20 million tons of iron, which amounts to about 40% of the current U.S. production rate, the FIT would require 2 million tons/year of hydrogen, making steel industry a large potential consumer of hydrogen.

The FIT will remove many of the shortcomings suffered by other alternative processes. Specifically, it will be operated with (a) direct use of iron oxide concentrate without the need for pelletization or sintering; (b) no cokemaking required; (c) high temperature conditions with no pellet sticking or disintegration problems; (d) low refractory problems; and (e) ease of feeding the raw materials.

The development of the FIT started with the verification of sufficient kinetic feasibility considering the fact that there are only a few seconds of residence time available in a typical flash reactor. The results of the kinetic feasibility work have been reported

Fig. 1 A sketch of a direct steelmaking process based on the Flash Ironmaking Technology (FIT).

in detail and the reader is referred to the literature (Chen et al., 2015; Elzohiery et al., 2017, 2021; Fan et al., 2016a,b, 2017, 2021; Wang and Sohn, 2015). Further, a laboratory flash reactor was operated in preparation of the construction and operation of a pilot-scale reactor, as described elsewhere (Elzohiery et al., 2020; Fan et al., 2016b; Sohn et al., 2009a), and a comprehensive computational fluid dynamics (CFD) model of the flash reactor operation was carried out (Elzohiery et al., 2020; Fan et al., 2016b). Upon the establishment of the kinetic feasibility and based on the success with the laboratory flash reactor as well as the CFD simulator development, a pilot-scale reactor test program was carried out, as described below.

Operation of a pilot-plant scale flash reactor

Here, we will describe a Pilot Flash Reactor operated at 1200–1600 °C with a concentrate feeding rate of 1–7 kg/h, shown in Fig. 2. This reactor was the first flash ironmaking reactor where the heat and reductant are produced by partial oxidation of hydrogen or natural gas with industrial oxygen.

Facility

The Pilot Flash Reactor consisted of a reactor vessel, a vessel roof, burners, a quench tank, off-gas piping, a flare stack, an off-gas analyzer, a gas valve train, a water cooling system, gas leak detectors, a concentrate feeding system, and human machine interface. Fig. 3 shows the main components of the reactor body.

The Human Machine Interface (HMI) consisted of the main programmable logic controller (PLC) and a computer. The main PLC was connected to all the different parts of the system and to the computer where the operator could monitor all the different parts and run the reactor. The programming in the main PLC was responsible for all the safety and emergency steps.

During the preheating stage, natural gas was burned with industrial oxygen to preheat the reactor at a ramp rate of 90–95 °C/h. The operating temperature range was 1200–1550 °C. During the actual operation in which iron ore concentrate was fed, natural gas and oxygen were fed at a pre-determined ratio through the main burner to start the partial combustion, which provide the heat needed to maintain the process temperature, and generate reducing gases H_2 and CO. Although the laboratory flash reactor tests indicated that operation with hydrogen is very similar to that with natural gas (Elzohiery et al., 2020; Fan et al., 2016b; Sohn et al., 2009a), the pilot reactor was operated only with natural gas for ready availability and low costs. Fig. 4 shows a screen shot that displayed and controlled all the parameters of the reactor operation. Further details of the operations of this pilot plant facility is available elsewhere (Elzohiery, 2018).

Fig. 2 The pilot plant with a Flash Reactor installed at the University of Utah.

Fig. 3 Schematic diagram of the Pilot Flash Reactor.

Results from pilot flash reactor runs

The results of the Pilot Flash Reactor runs are expected to help in designing the industrial reactor, including the identification of the difficulties and how to improve the various aspects of operation. This reactor was simulated by CFD to optimize the operating conditions to achieve a high reduction degree at the optimum conditions and reactor dimensions to be used in an industrial reactor (Abdelghany et al., 2019). Table 1 shows the results of the runs performed in the reactor using industrially produced, as-received magnetite concentrate with a particle size range less than 90 μm .

Fig. 4 The controlling screen for the HMI for the pilot flash reactor.

Different experimental runs were made in this reactor to yield a wide range of reduction degrees deliberately at less than complete reduction to better examine the effects of the operating conditions and validate the CFD model under different conditions. The experiments in the pilot plant were performed at different temperatures and reducing powers of the gas with the aim of obtaining sufficient data to design the industrial flash reactor. In order to represent the data obtained from the reactor, the nominal residence time for the particles was calculated based on the total volumetric flow rate of the gases at the experiment temperature and the total volume of the reactor vessel which was 1.01 m^3 . When the velocities of the gases and the particles at the injection points are taken into consideration, the actual residence time would be shorter.

The results showed good reproducibility within $\pm 5\%$ of the average reduction degree. This represents a very high degree of reproducibility, considering the complexity of the operation and design of this large unit.

Flow sheet development, process simulation, and economic feasibility

Based on the potential advantages discussed above and the results of the process feasibility studies, detailed flow sheets for different versions of the new process depending on the fuel type and economic analysis have been developed by Pinegar et al. (2011, 2012, 2013a,b).

Energy requirement for the standard case operation compared with that of the average blast furnace process, assuming that hydrogen and coking coal were the starting raw materials, indicated that the proposed process would consume 57–60% less energy. However, it is noted that the energy for hydrogen or coal production must be added for a comprehensive comparison of the energy requirement. An economic feasibility analysis was also performed (Pinegar et al., 2011, 2013b).

The flow sheet development and process simulation as well as economic analysis for the process based on natural gas is available elsewhere (Pinegar et al., 2012, 2013a,b). Here, those analyses for the process using hydrogen (HyFIT) will be summarized (Pinegar et al., 2011).

Table 1 The results of runs performed in the Pilot Flash Reactor.

Inner wall temperature (°C)	Magnetite concentrate feeding rate (kg/h)	Gas flow rate (SLPM) ^a		H ₂ excess driving force (EDF)	Nominal residence time (s)	Reduction degree (RD) (%)
		Main burner				
		NG (SLPM)	O ₂ (SLPM)			
1200–1130	5.0	404	321	0.76	12.5	65

1410–1320	5.0	300	210	0.82	14.9	82

^aThe flow rates of NG and O₂ in the pilot burner were 9.6 and 37.6 SLPM, respectively. The flow rate of N₂ in the powder feeder was 10.7 SLPM.

Material and energy balances

Tables 2 and 3 summarize the material and energy balances for one-step and two-step processes operated with the ironmaking reactor temperature of 1500 °C as the standard case. Hydrogen preheating temperature was set to 900 °C for the one-step process, and 750 °C for the two-step process. Material and energy flows for both processes at the standard case with all the stream values and conditions can be found elsewhere (Pinegar et al., 2011).

In this work, hydrogen and coking coal were chosen to be the starting raw material of fuel/reductant reagent for the energy requirement comparison. However, as for the comparison of energy consumption, it is noted that a more comprehensive evaluation of the energy requirement of the proposed process and the blast furnace is complicated and depends on the choice of starting raw materials. Depending on the starting material, the energy required for raw material extraction should also be included.

When hydrogen is used as the starting fuel/reductant material, energy requirements are 5.48 and 5.03 GJ/ton of iron, respectively, for the one-step and two-step processes (HyFIT). These energy requirements were obtained using the higher heating value of hydrogen used as the fuel and reductant. Compared with the average blast furnace process assuming that coking coal is the starting material, the proposed processes consume 57% and 60% less energy, respectively.

In the proposed process, flux calcination was assumed to be performed separately before the flux was fed to the reactor so that the reactor off-gas would not be diluted by carbon oxide gases.

The energy requirement was examined at different operating conditions. When the ironmaking reactor operating temperature rises to 1600 °C, energy requirements based on the higher heating value of hydrogen become 5.86 and 5.32 GJ/ton of iron for the one-step and two-step ironmaking processes, respectively.

Although the energy requirement of the proposed process HyFIT based on purchased hydrogen was estimated to be much smaller than the average blast furnace process, even with a higher operating temperature and heat loss, a comprehensive comparison of energy requirement including the energy consumption for raw material extraction such as coal mining, natural gas pumping, is very complicated due to diversity of operation and processes and thus beyond the scope of this work.

Note on “Energy Requirement”: It must be kept in mind when comparing the “energy intensity values” or “energy requirements” to clearly understand the energy items included in these values (Sohn and Olivas-Martinez, 2014). There are currently different approaches for selecting energy items to include in the overall “energy requirements” when an input fuel also serves as a reactant.

For a process involving heat generation from fuel combustion, the choice of which endothermic reactions to select to compute the energy requirement can cause confusion. The essential question is whether the heating value of a reactant that is also burned to generate process heat should be added as an item in the “energy requirement.” Some investigators include this item (Fruehan et al., 2000; Remus et al., 2013; Stubbles, 2000) and others do not (Burgo, 1999; Pinegar et al., 2011, 2012, 2013a). The presented “energy

Table 2 Material balance for commercial-scale one-step and two-step ironmaking processes (HyFIT) with the operating temperature of 1500 °C and the hydrogen preheating temperature of 900 °C in the one-step process and 750 °C in the two-step process, compared with that for the average blast furnace process.

^aThis number does not include the carbon dioxide emission from ore/coke preparation.

^bThe actual amount may be slightly higher if heat loss from the hydrogen recycling step is considered.

^cWater requirement for US Steel's Fairfield No. 8 Blast Furnace (production rate: 5500 tons/day) (United States Steel Corporation, 1985; Camlic and Goodman, 1997) including water for top gear, stack plates, bosh channels, tuyere jacket, tuyeres and tuyere coolers, hearth and subhearth, and stove valves, as the reference years of water usage is older than that of the production rate, this number may be somewhat larger than the number for a modern plant.

requirement" varies with the selected approach. The choice is arbitrary, but one should indicate explicitly which approach is used in showing the energy calculations, especially in comparing different processes.

The net differences in the energy requirements between technologies are not strongly affected by the selection of calculation approaches if the same method is used for different technologies, but the consumption values for individual processes themselves depend on them. Thus, whether the heat of combustion of a reactant that can also be burned is included in the energy requirement should be clearly indicated. It will make it much more definitive to indicate the amounts for "process energy" that contains only the heating value of the fuel and "reductant energy" ("feedstock energy" in petrochemicals production) that includes the heating value of the substance serving as a reactant.

For detailed description of these different calculation methods and discussion on the subject, the reader is referred to (Sohn and Olivas-Martinez, 2014). An additional caution that follows from this consideration is that the comparison of different ironmaking processes for their energy requirements should only be done with the values obtained using the same method by the same investigators. In other words, the energy requirement value obtained by one investigator for a certain ironmaking process should not be compared with a value obtained by another investigator for a different ironmaking process without carefully checking the bases of the calculations.

The energy values presented above in this article are based on the "process energy," i.e. they do not include the heat of combustion of the reductants that react with iron oxide.

Summary

The use of hydrogen in the novel ironmaking process would greatly reduce carbon dioxide emissions and energy consumption as well. Conversely, the steel industry is a huge potential consumer of hydrogen from the viewpoint of a developing hydrogen economy. Based on the tremendous scale of demand for steel, it appears that the steel industry and the development of hydrogen production would be a great match, especially when hydrogen is produced from carbon-free sources of energy such as nuclear or solar energy.

This article describes the development of a novel ironmaking technology based on flash reaction, which is expected to require up to 60% less energy in the ironmaking step with little carbon dioxide emissions when operated using hydrogen (HyFIT). Process flow sheets for the commercial-scale novel suspension ironmaking process based on purchased hydrogen were constructed and simulated. The proposed process was modeled in two configurations: one-step and two-step processes in which the number of iron ore reduction reactor is different. Simulation was performed under various operating conditions to examine the effect of operating conditions on the fresh hydrogen amount which would affect the economic feasibility greatly due to expensive hydrogen price.

Table 3 Energy balance for commercial-scale one-step and two-step ironmaking processes (HyFIT) with the operating temperature of 1500 °C and the hydrogen preheating temperature of 900 °C in the one-step process and 750 °C in the two-step process compared with that for the average blast furnace process.

		One-step process	Two-step process	BF process ^a

	Pelletizing			3.01 (Stubbles, 2000)
	Sintering			0.65 (Stubbles, 2000)
	Cokemaking			2.02 (Stubbles, 2000)
	Total-ironmaking ^d	5.48	5.03	12.7
	CaCO ₃ and MgCO ₃ decomposition at 1000 °C	0.26 ^e	0.26 ^e	

^aEnergy balance was calculated by METSIM based on the material balance.

^bFuel combustion energy generated in the process was calculated by subtracting the energy used for iron ore reduction from the balance of heats of formation of all output components from the entire system and input components into it. The higher heating value of natural gas was used for this calculation. If the lower heating value is used, the total energy requirements for the one-step and two-step processes will decrease, respectively, to 3.74 and 3.49 GJ/ton of iron.

^cHeat loss in the heat recovery step was estimated to be 5% of the energy difference between the hot off-gas (calculated to be 426 °C) and cooled reactor off-gas (90 °C), and the rest was estimated to be the recovered energy.

^dHydrogen and coking coal are considered as the starting raw materials. This energy requirement comparison does not include electrical power required for the plant operation.

^eThe energy requirement for CaCO₃ and MgCO₃ calcination to generate CaO and MgO for the flux was calculated by METSIM. Calcination was assumed to be done at 1000 °C separately from the ironmaking process.

^fIf the temperature of iron and slag is replaced by 1600 °C (same as the blast furnace process), the total energy for the one-step and two-step processes increases to 5.86 and 5.32 GJ/ton of iron, respectively, by the increased sensible heat of iron and slag.

^gHeat losses in a heat exchanger were assumed to be 5% of the total sensible heat of input streams.

Energy requirement for the standard case operation compared with that of the average blast furnace process, assuming that hydrogen and coking coal were the starting raw materials, indicated that the proposed process HyFIT would require 57% and 60% less energy, respectively, for the one-step and two-step processes. However, it is noted that the energy for hydrogen or coal production must be added for a comprehensive comparison of the energy requirement.

Acknowledgments

The authors wish to thank all other graduate and undergraduate students and postdoctoral associates, too many to name all, who over the years participated in various aspects of the development of the Flash Ironmaking Technology described in this article. The support and resources from the Center for High Performance Computing at the University of Utah are gratefully acknowledged. We also acknowledge the financial support from the U.S. Department of Energy under Award Number DE-EE0005751 with cost share by the American Iron and Steel Institute (AISI) and the University of Utah.

Introduction

Research on solar and nuclear high-temperature ($> 600\text{ }^{\circ}\text{C}$) process heat applications is largely concerned with the production of hydrogen (Angulo et al., 2012; Barlev et al., 2011; Forsberg, 2020; Kuhr, 2008; Nowotny et al., 2005). Green hydrogen production can be considered a key process, since the hydrogen can again be converted into synthetic fuels that can be used without having to change a large part of the present fossil fuel dominated energy infrastructure. Using high-temperature solar and nuclear heat for mineral processes such as calcination may also be attractive though, as this practice has the potential to mitigate fuel combustion altogether and can dramatically increase energy efficiencies if compared to using synthetic fuel from green hydrogen. Besides, mineral products just like hydrogen can be produced with excess power from solar or nuclear power plants.

A significant mineral process that could profit from solar and nuclear process heat is calcination. Mineral calcination that is for instance essential for cement production, accounts for some 5% of all anthropogenic carbon dioxide (CO_2) emissions per year (Worrel et al., 2001). It is an energy intensive service that is notoriously challenging to provide without adding CO_2 to the atmosphere (Davis et al., 2018). More than half of the CO_2 released during mineral calcination results from burning fossil fuels for heat generation, while the other half is a product of the calcination reaction itself. The calcination reaction is provided below for limestone (Latin: calcinare = to burn lime) that is calcinated for cement production.

It is worth noting that the calcium oxide (CaO) is not stable and cement hydration products reabsorb CO_2 from the atmosphere over time in a process called carbonation. Xi et al. (2016) estimate that carbonating cement materials reabsorb a bit more than 20% of the initial direct CO_2 emissions from calcination and heat generation that amounted to some 2.5% of global anthropogenic CO_2 emissions in 2013. If it would be possible to further eliminate direct CO_2 emissions during calcination, carbonating cement materials would not only reabsorb one fifth of their CO_2 emissions but could act as a substantial global CO_2 sink.

Direct solar calcination

Concentrated solar power plants can reach the high temperatures ($550\text{--}1150\text{ }^{\circ}\text{C}$) required for the calcination of lime. At the World Fair of 1904 in St. Louis (MO, United States) Gomes Himalaya presented a prototype of an invention he patented 3 years earlier (Gomes Himalaya, 1901) that concentrated solar radiation for industrial use. He melted metals in front of spectators and received several awards for his invention (Rosa, 2019) that is depicted in Fig. 1.

Several research groups are actively working on solar calcination using concentrated solar radiation just as Gomes Himalaya proposed. Flamant et al. (1980) presented several solar reactor designs suitable for solar decarbonization of lime (CaCO_3). More recently, Costa Oliveira et al. (2019) conducted experiments proving that solar calcination is indeed possible despite the low solar absorptance of the mineral feed that make it challenging to realize large mineral throughputs. Costa Oliveira et al. (2019) envision a rotary kiln furnace similar to the ones used for fossil fuel powered calcination but heated by the power of the sun using concentrated solar radiation only. Such solar rotary kiln designs have been reviewed for different industrial processes by Alonso et al. (2017). Particularly comprehensive experiments were conducted by Meier et al. (2004, 2005a,b, 2006) with an indirectly heated multitube rotary kiln calcination furnace. Besides technical feasibility studies an economic evaluation (Meier et al., 2005b) was conducted that indicate that solar calcination, as a result of the relatively low material throughput, but the high quality of the final product, could supply a niche market such as pharmaceuticals that require relatively low quantities of high-quality lime.

Fig. 2 Simplified cross section of the externally heated closed helical coil design (top) and the tube-in-tube closed helical coil design (bottom). Haneklaus N, Zheng Y and Allelein HJ (2017d) Stop smoking—Tube-in-tube helical system for flameless calcination of minerals. *Processes* 5(4): 67.

Indirect flameless calcination

Traditionally, the fuel combustion process and the calcination reaction take place together to enhance heat transfer in a calcination furnace. For a significant reduction of CO₂ emissions radically new systems will have to be developed and tested that might challenge this approach. Haneklaus et al. (2017a,b) coined the term “flameless” for calcination reactions by other means than fossil fuel combustion. Fossil fuel powered (mostly natural gas) systems using indirect heat transfer, i.e., separate fuel combustion and calcination are already occupying a niche market supplying higher quality calcination products such as the high-quality lime needed for pharmaceuticals. Sceats et al. (2014) envisioned a system for indirect calcination of minerals using a helical tube reactor. Sceats et al. (2014) proposed to choose the pitch of the helical tube in a way that it is equal to the outer diameter of the reactor tube, so that a closed coil is formed that can be externally heated. Fuel combustion, electrical heating or a heat transfer fluid (HTF) were foreseen in the externally heated closed coil design. Based on the closed coil tube design Haneklaus et al. (2017a) proposed using a tube-in-tube helical design for the calcination of minerals. Using a tube-in-tube reactor design may be beneficial in a way that the area for heat input from the HTF can be doubled as depicted in Fig. 2.

According to He et al. (2020) the 3rd generation of concentrated solar power plants that is currently being developed will use molten salts, He, supercritical CO₂ and particles as heat transfer fluids that will allow operating temperatures above 700 °C. These temperatures are still lower than the about 1000 °C used in the majority of lime calcination operations at the moment. Increasing the volume to surface ratio by using fine powder and inducing steam can reduce calcination temperatures. Sceats et al. (2014) conducted feasibility tests with batches of 0.2–2.0 kg finely ground (125 μm) magnesite ore (97% MgCO₃). It could be shown that the residence time and the required calcination temperature can be reduced to a few seconds and <500 °C if the material is finely ground and superheated steam also at <500 °C is added.

The calcination designs of both Sceats et al. (2014) and Haneklaus et al. (2017a) are designed to work with fine powder and use superheated steam to further reduce processing temperatures. A cross section of the whole tube-in-tube flameless calcination system

proposed by and Haneklaus et al. (2017a) is provided in Fig. 3 (left) and a schematic overview of the system with HTF in- and outflow is presented on the right of Fig. 3.

The heat transfers from the outer tube (blue, in cross section) to the inner reactor tube (yellow, in cross section). The finely ground mineral feed is mixed with steam to further reduce the required calcination temperature and time in the reactor tube.

With a market volume of a bit more than USD 200 billion and a production of over 5 billion tonnes the cement industry is the largest calcination industry in the world. The relatively high calcination temperatures might not make it the first calcination industry that could profit from flameless calcination, however. Phosphate rock often contain large amounts of calcite (CaCO_3) and dolomite ($\text{CaMg}(\text{CO}_3)_2$) that need to be removed prior to the production of mineral fertilizers. Calcination of phosphate ores to remove carbonates is expensive as a result of the high costs for energy. Phosphate rock calcination is practiced for approximately 10% of phosphate rock, mostly to improve final product quality by removing minor amounts of carbonates and organic matter (Ruan et al., 2019).

For fine powder of dolomite ($\text{CaMg}(\text{CO}_3)_2$), calcination temperatures with superheated steam range from 500 to 650 °C and usually take place in a single endothermic reaction described in Eq. (2) (Olszak-Humienik and Jablonski, 2015).

The required calcination temperatures for dolomite can be comfortably reached using inexpensive solar salt ($0.6 \text{ NaNO}_3 + 0.4 \text{ KNO}_3$) that is already in use in a number of concentrated solar power plants today. Interestingly the global phosphate rock reserves reported by the US Geological Survey (USGS) (2020) by country are largely located in regions with excellent to good solar radiation as indicated in Fig. 4.

Besides concentrated solar power, high temperature reactors are another greenhouse gas lean energy source that are capable of heating a HTF (steam, molten salt, etc.) to temperatures relevant for flameless calcination. Among the various high temperature reactors capable of reaching the required high temperatures (> 600 °C) for flameless calcination of phosphate rock (Haneklaus et al., 2016), high temperature gas-cooled reactors (HTGRs) are presently the most mature technology. HTGRs such as the HTR-PM demonstration plant that is currently under construction in Shandong province in China, have been under development since the 1960s (Reitsma et al., 2018). Fig. 5 provides an overview of past and present HTGR projects by country.

Despite the maturity of HTGRs and the demonstration plant presently erected in Shandong Province, China (Zhang et al., 2016) it will still take considerable efforts until HTGRs or any other group of high temperature reactors can be employed for other services than electricity production. The very high temperatures will further present new material challenges that need to be overcome (Sabharwall et al., 2013).

Keeping in mind that calcination accounts for some 5% global anthropogenic CO_2 emissions (Worrel et al., 2001) taking on these challenges is justified. Fig. 6 provides a brief overview of the plant layout for flameless calcination with the proposed tube-in-tube helical reactor and concentrated solar power (top) as well as high temperature reactors (bottom) as power sources.

The technical feasibility of flameless calcination with concentrated solar power and high temperature reactors has yet to be proven. The work by Sceats et al. (2014) for Calix Ltd. from Australia resulted, among other things, in the Leilac 1 and 2 ("Low Emissions Intensity Lime and Cement") projects (Hills et al., 2017; Hodgeson et al., 2018) that received nearly EUR 30 million in funding from the EU to build a prototype calcination furnace that promises to greatly reduce CO_2 emissions. The projects show the tremendous interest of the European mineral processing industry as well as the EU cleaner mineral processing technologies.

Fig. 3 Overview of the tube-in-tube helical system for flameless calcination proposed by Haneklaus et al. (2017a). Haneklaus N, Zheng Y and Allelein HJ (2017d) Stop smoking—Tube-in-tube helical system for flameless calcination of minerals. *Processes* 5(4): 67.

Fig. 4 Global solar radiation potential for concentrated solar power plants and 10 countries with the largest phosphate rock reserves.

Fig. 5 Past and present high temperature gas-cooled reactor (HTGR) projects by country. Reitsma F, Woods P, Fairclough M, et al. (2018) On the sustainability and progress of energy neutral mineral processing. *Sustainability* 10(1): 235.

Based on the estimated heat requirements ($3.6 \text{ MW}_{\text{th}}$ in total; $2.6 \text{ MW}_{\text{th}}$ for 1.45 kg/s calcite that needs to be heated to $600\text{--}750^\circ\text{C}$ and $1.0 \text{ MW}_{\text{th}}$ for $0.05\text{--}0.5 \text{ kg/s}$ superheated steam at $0.02\text{--}0.3 \text{ MPa}$) of the flameless calcination using the tube-in-tube helical system, an adequate cogeneration layout for power supply with a HTGR was designed by BrivaTech Consulting as shown in Fig. 7.

The brief analysis showed that a HTGR with $180 \text{ MW}_{\text{th}}$ would be enough to provide high temperature process heat and superheated steam for up to 46 calcination units that could process approximately 5762 t mineral feed (calcite/dolomite or other) per day. In the analysis, electricity is only generated for the cogeneration system itself. Different configurations with fewer calcination units and more electricity production could of course be considered.

Average calcination furnaces process 1 t calcite (CaO_3) per day and emit between 1.1 and 1.6 t CO_2 per tonne lime product (EuLA, 2014). In the European Union, approximately 68% of the emitted CO_2 emissions result from the calcination reaction itself with another 30% being a result of fuel related emissions and 2% are indirect CO_2 emission associated with electricity production. Fossil-based solid fuels (51%), natural gas (34%), waste (8%), oil (5%) and biomass (2%) are used to generate the required heat (EuLA, 2014). Flameless calcination could reduce direct CO_2 emissions in mineral calcination by 32% and if exhaustion gases are captured as indicated in Fig. 3, CO_2 emissions could be largely eliminated during mineral calcination.

Economics of flameless calcination

Besides the technical feasibility, Haneklaus et al. (2017b) conducted an economic assessment of flameless phosphate rock calcination with concentrated solar power and high temperature reactors. The assessment compared heating costs (USD per tonne calcine) and net present values (NPVs) at different heat selling prices (USD 15, 30 and 45 per MWh_{th}). Cost estimates were based on literature values of the costs for electricity production of the GemaSolar concentrated solar power plant in Spain (Burgaleta et al., 2012)

Fig. 6 Proposed flameless calcination plant layout with concentrated solar power (top) and high temperature reactors (bottom).

Fig. 7 High temperature gas-cooled reactor (HTGR) cogeneration system for flameless phosphate rock calcination. Source: BriVaTech.

(capital costs of USD 11,445/kW_e and O&M costs of USD 38.15/MWh_e for the 1st of a kind) and the HTR-PM (High-Temperature Gas-Cooled Reactor Pebble-Bed Module) currently under construction in China (Zhang et al., 2016) (capital costs of USD 5000/kW_e, O&M costs of USD 14.54/MWh_e and fuel costs of USD 9.60 MWh_e for the 1st of a kind).

The economic assessment revealed that natural gas-fired kilns calcine phosphate rock at lower costs than the flameless system with concentrated solar power/high temperature reactors. This is no surprise given the current costs for concentrated solar power plants and high temperature reactors. The study did further show that flameless calcination could become cost competitive if potential future cost reductions for concentrated solar power plants (capital costs of USD 5723/kW_e and O&M costs of USD 19.08/MWh_e for the nth of a kind) and high temperature reactors (capital costs of USD 2500/kW_e, O&M costs of USD 14.54/MWh_e and fuel costs of USD 9.60 MWh_e for the nth of a kind) as they are foreseen by the International Renewable Energy Agency (IRENA) and the reactor developers can be realized, low-interest rates of 5–10% and relatively high natural gas prices above USD 7.5–10 per mmBTU are present. Besides, the study considers a carbon tax of USD 30/t CO₂ emitted. Even at these benevolent conditions a flameless calcination system will always be more complicated than much simpler gas-fired kilns that are around for centuries and potential consumers interested in flameless calcination will need to consider if the additional risks can be justified (Haneklaus et al., 2017b).

Energy neutral mineral processing

It is well-known that phosphate rock can contain natural uranium at elevated concentrations of 70–200 mg/kg (Haneklaus et al., 2017c,d). This accompanying uranium can be recovered and used as raw material to produce nuclear reactor fuel. To illustrate the significant concentrations of natural uranium in phosphate rock, Haneklaus et al. (2015a,b) and Haneklaus and Schnug (2016) proposed energy neutral mineral processing of phosphate rock to mineral fertilizers in a way that uranium is recovered during phosphate rock processing and after enrichment and fuel manufacturing used as nuclear reactor fuel in high temperature reactors that provide electricity and process heat for mineral processing with unconventional uranium recovery. If the amount of recovered uranium is sufficiently high to operate the nuclear reactor the process can be labelled energy neutral as illustrated in Fig. 8.

Since the introduction of energy neutral mineral processing the quantities of unconventional uranium that could be recovered during phosphate rock processing in Argentina (López et al., 2019), China (Shang et al., 2021; Ye et al., 2019), the European Union (Tulsidas et al., 2019) and the United States (Kim et al., 2016; Steiner et al., 2020) have been evaluated. Recovering uranium from calcinated phosphate rock can be more economic since a cleaner phosphoric acid is produced after calcination compared with phosphoric acid produced after flotation of phosphate rock. Most importantly flameless calcination and uranium recovery are independent processes that can be further developed in parallel.

Conclusions and outlook

Realistically, present day high temperature reactor technology can support high temperature process heat applications in the range of 700–800 °C. Such temperatures may not be sufficient to calcinate lime for cement production that decomposes at temperatures of 500–1150 °C and is usually performed at approximately 1000 °C. It could, however, be shown that steam can be used to reduce the calcination temperature and it is further well-known that dolomites and other minerals can be decomposed at temperatures below 800 °C. Of particular interest may be the calcination of selected phosphate rock that can occur at temperatures well below

Fig. 8 Schematic overview of energy neutral mineral processing. Reitsma F, Woods P, Fairclough M, et al. (2018) On the sustainability and progress of energy neutral mineral processing. *Sustainability* 10(1): 235.

Fig. 9 Path forward for flameless calcination.

800 °C. Ironically most phosphate rock reserves are located in regions with excellent to good solar radiation for concentrated solar power plants such as northern Africa (more than 75% of all phosphate rock reserves are located in Morocco). **Fig. 9** provides an outlook on the next steps of making flameless calcination (with or without uranium recovery) a reality.

The first lab-scale experiments that can support flameless calcination were conducted in Tunisia recently (Abbes et al., 2020) and there is generally enough data to estimate the required calcination temperatures of phosphate rock from different deposits. As a next step, flameless calcination, most likely with natural gas heating a HTF, will need to be performed on pilot plant- and subsequently demonstration plant scale before this technology can be used for industrial applications that are then powered by concentrated solar power and high temperature reactors.

Glossary

AEC Atomic Energy Commission US government agency, successor to the Manhattan Project and succeeded by the Energy Research and Development Agency (ERDA) and by of the Nuclear Regulatory Commission (NRC).

AIP Air Independent Propulsion, not needing air for propulsion.

knot Unit of nautical speed, one nautical mile per hour = 1.15 statute miles per hour = 0.51444 m/s = 1.852 km/h.

MIT Massachusetts Institute of Technology, university in Cambridge, Massachusetts, United States.

MWe/MW_{shaft} Megawatts electric/Megawatts shaft, measures of the output of usable work from a heat engine, such as a steam turbine or a diesel engine.

MW_{th} Megawatts thermal a measure of the thermal input to a heat engine from a nuclear reactor, boiler or diesel fuel combustion.

NPT Treaty on the Non-Proliferation of Nuclear Weapons initially signed in 1968 and came into force in 1970.

Q244 French submarine reactor project.

SSBN Ballistic Missile Nuclear-powered Submarine (US Navy designation, SS = SubSurface).

SSGN Guided Missile Nuclear-powered Submarine (US Navy designation)

SSN Nuclear-powered Attack Submarine

t Metric ton, 1000 kg.

TEU Unit of measure for container ship capacity, 20-foot Equivalent Units, a standard container 20' long, 8'6" high and 8' wide (6.096 m × 2.59 m × 2.438 m). This unit continues to be used although most containers are now 40 ft in length and amount to 2.0 TEU. Other containers are 45, 48 or 53 ft in length and some are 9.5 ft. in height. All containers have standardized maximum weight limits. While actual loaded weights of course vary, the average gross weight is 14 t/TEU.

The need and the beginning

Submarine warfare during world war II

Germany used submarines to devastating effect in [World War II](#). During the first few years of the War, their U-boat fleet scored unprecedented success. These diesel electric boats had to surface periodically to charge their batteries and met the same fate. In 1943, hoping to hide their U-boats from the increasingly devastating air patrols, Germany perfected an idea that had been floating around for some time—the use of a breathing tube to allow running on diesel power just below the surface, thus also keeping batteries fully charged. They dubbed it the “snorkel” but the innovation also presented several problems to their users. A U-boat with a snorkel raised was limited to a speed of 6 knots to avoid damage to the tube and its sound-detection gear was useless with the diesel engine in operation. The increasingly sophisticated detection equipment deployed by the Allies led to severe losses and German designers began to fully realize the potential of a truly submerged boat. In response to the mounting U-boat losses, in 1943, a submarine research center was created by the Germans at Blankenburg in the Harz Mountains with the aim of producing an operational high-speed U-boat capable of prolonged submergence.

Air independent propulsion systems

Air-independent propulsion (AIP) is any [marine propulsion](#) technology that allows a non-nuclear [submarine](#) to operate for longer periods in submerged condition. Air Independent Propulsion (AIP) technology became the holy grail of submarine design ever since German engineer Hellmuth Walter first began experimenting with his high purity hydrogen peroxide powered engine in the early 1930s. A Closed-cycle Diesel Engine in a submarine can be operated conventionally on the surface, but can also be provided with [oxidant](#), usually stored as [liquid oxygen](#), when submerged. Closed-cycle steam turbine is the propulsion system with heat generated by [ethanol](#) and oxygen stored at a pressure of 60 [atmospheres](#). A number of countries are working on different AIP systems; fuel cells and lithium batteries are most predominant. Clearly, no AIP technology currently resolves all submarine challenges.

Nuclear propulsion

After the discovery of nuclear fission in 1939 ([Michel, 2000](#)), the original interest of the US Government in harnessing the power of the atom was not to produce an atomic bomb but to devise nuclear propulsion for ships. Before the outbreak of the Second World War, US Naval Research Laboratory was engaged in studying the idea of building a propulsion plant for ships. To build a light weight, small nuclear plant for ships, the Laboratory developed the first method of separating the essential isotope of Uranium 235 from natural uranium. This was the thermal diffusion method which did not prove to be as practical as the gaseous diffusion later developed at Oak Ridge.

Once the decision was made to develop an atomic bomb, the initial idea of the propulsion plant was shelved and the bomb project was given priority. After the war, when the subject of nuclear propulsion was rekindled, there were those who believed that atomic reactors with large amounts of steel-shielding and concrete could never be carried aboard ships. They had in mind the very large reactors at Hanford, built for producing plutonium for bombs during the war. Others thought that humans could not live and work in close proximity to radiation sources. Fortunately, there were those who thought that these problems could be overcome; the credit must go to them for the success of atomic submarines and even the first commercial nuclear-powered ship “Savannah,” which was commissioned a few years after the first nuclear propelled submarine “Nautilus.”

Development in different countries

United States

Toward the end of 1945, the idea of an atomic powered submarine was fascinating to Captain Hyman Rickover who led the program and was later promoted to Admiral. Since the atomic reactor did not require oxygen, for the first time the Navy could have a true submarine, which could stay underwater indefinitely without contact with the surface. The final limits would be for replacing equipment that wears out, the fatigue limit of the hull, crew morale and the amount of food it could carry. Advantages were tremendous; it could sneak up to an enemy surface ship at full speed, destroy and escape while submerged.

Submarines

Captain Rickover concluded that the atomic powered submarine was the first order of business for the United States Navy. If a reactor could be built to fit in a small submarine, it was sure to be fitted in any larger ship. He could convince the authorities that the submarine project, like the hydrogen bomb, would become a key to the nation's defense; civilian nuclear power program would become easier once the nuclear propulsion was developed. Captain Rickover had by then concluded that the reactor would have to be thermal/slow neutron type and use water as a coolant. At this stage the Westinghouse Electric Corporation was brought on board; Westinghouse was required to set up a laboratory with requisite scientific personnel to carry out experiments on a heat exchanger system for an atomic power reactor similar to the General Electric program, but the difference was that Westinghouse would be working with pressurized water as the coolant instead of low-pressure sodium being used by General Electric for the core coolant. Conducting experiments was not enough; they had to work on the most difficult task, the reactor itself. This was a step in the right direction; two of the then largest and most capable firms were competing with each other toward this end. Equally important was the shielding, which would protect personnel from the extraordinary amounts of radioactivity generated within the reactor fuel. A series of experiments were performed in research reactors to test the performance of various shielding materials. There was a challenge to metallurgists to find a metal that could withstand high stress while operating at high temperatures and also did not absorb neutrons. This metal was a strange new metal called zirconium and large-scale production had to be started. In addition, the project also required substantial quantities of beryllium (Be) and later hafnium (Hf); Be slows-down fast neutrons and Hf absorbs neutrons. Both materials can withstand high temperatures. Captain Rickover became the "Chief" of the naval reactor branch of Atomic Energy (Anand et al., 2016).

The contract between the Atomic Energy Commission and Westinghouse was formalized; AEC agreed to provide funds for the construction of an atomic power laboratory—the Bettis Laboratory, in conjunction with the scientists of their Argonne National Laboratory. The Bettis Lab was built by Westinghouse at a site outside Pittsburgh where physicists and engineers assembled to design and build the thermal water-cooled submarine reactor. With the backing from the Navy and the Atomic Energy Commission, the educational staff at the Massachusetts Institute of Technology arranged a special 1-year course in nuclear engineering.

The design of the "Reactor Core" consisting of fuel elements, control and shut off rod mechanisms housed in the reactor pressure vessel is probably the most difficult task for the reactor engineers. Evolving a practical design of fuel elements proved to be an especially difficult task. Not until March 1950 did Argonne and Bettis decide that it would be feasible to assemble a fuel element consisting of uranium zirconium alloy clad with zirconium.

The biggest problem was to fit the bulky atomic reactor inside the hull; some felt that the reactor should be partly outside the hull away from the ship like an aircraft engine on the wings and others argued that the reactor should be inside the hull in the designated "reactor compartment" thus containing all the radioactivity inside the compartment. Finally, Westinghouse solved the problem of accommodating the reactor in the hull. When a new type of propulsion plant is built for a ship, aircraft or any other vehicle, it is mandatory to first build an experimental version on land to ensure it performs properly. Captain Rickover insisted that this land-based plant be built inside the submarine hull on land. If Westinghouse painstakingly built a land-based plant, checked it thoroughly, and then redesigned it to fit in the submarine, the two stages would take years to complete. The Captain's idea was to build two plants simultaneously; one, a land-based prototype, and the second would go into the submarine. The schedule would be worked out in such a way that the sea-going reactor would lag slightly behind the land-based reactor so that any changes and improvements could be incorporated into the sea-going version expeditiously.

Nautilus and seawolf

Captain Rickover convinced the Electric Boat Company to be a sub-contractor to the Westinghouse Electric Corporation in designing and building the desert bound, land-based prototype submarine and its machinery. GE reoriented its program with emphasis on a fast reactor for the submarine and the Electric Boat Company readily agreed to assist GE in the ship building aspects of the project as they were doing for Westinghouse.

To avoid confusion, labels were put on both the projects; Westinghouse project was named STR short for "submarine thermal reactor" and GE project as SIR for "submarine intermediate reactor." The land-based reactor and the sea going version of Westinghouse STR, were named Mark One and Mark Two, respectively, while the GE's SIR were named Mark A and Mark B for the land based and sea going version, respectively. A typical flow diagram of a propulsion reactor is shown in Fig. 1.

By 1951, Mark One was under construction near Arco, Idaho at the National Reactor Testing Station (NRTS), and Mark Two was about to be started at Bettis Atomic Power Laboratory by Westinghouse. Electric Boat Company started the plans for construction of the submarine itself. The keel of the "Nautilus" was laid on June 14, 1952 in Groton, Connecticut. In May 1953, the land-based prototype was started in the NRTS. It performed much better than expectations and started "nonstop" long runs. The work on

Fig. 2 Mark one, the land based plant. https://en.wikipedia.org/wiki/File:Nautilus_core.jpg, <https://en.wikipedia.org/wiki/File:Nautiluscore.jpg>. This is a work of the U.S. federal government, it is in the public domain in the United States. Public Domain Mark 1.0.

"Nautilus" progressed rapidly. The submarine was launched on January 21, 1954. On January 3, 1955 the Mark Two reached full power. On January 17, 1955, as the Nautilus slipped down the Thames, a signalman on the submarine blinked to the escort tug "Skylark" "UNDER WAY ON NUCLEAR POWER." **Fig. 2** shows the Mark one, the land-based plant, and **Fig. 3** shows the launching of Nautilus.

The GE's Mark A and Mark B propulsion plants were also commissioned soon thereafter. The Submarine Intermediate Reactor (SIR) nuclear plant designed by General Electric's Knolls Atomic Power Laboratory was designated S1G and Seawolf's plant as S2G. The Seawolf's keel was laid on 7 September 1953 by the Electric Boat division of General Dynamics Corporation in Groton, Connecticut. Seawolf was launched on 21 July 1955 and commissioned on 30 March 1957; its propulsion system was more technologically advanced. It was carrying a liquid sodium cooled and more powerful **epithermal** reactor and a superheated steam power plant. The Nautilus carried the alternative light water reactor and saturated steam plant. In Seawolf, the size of the machinery in the

Fig. 3 Nautilus launched. https://en.wikipedia.org/wiki/File:Nautilus_core.jpg, <https://en.wikipedia.org/wiki/File:Nautiluscore.jpg>. This is a work of the U.S. federal government, it is in the public domain in the United States. Public Domain Mark 1.0.

engineering spaces was reduced by about 40% relative to that of Nautilus. However, the USS Seawolf was plagued by super heater problems, with the result that the USS Nautilus delivered far superior performance. This, and the risks posed by liquid sodium in the event of an accident at sea, led Admiral Rickover to select the PWR as the standard U.S. naval reactor type. The S2G was removed from USS Seawolf and replaced by the [S2Wa reactor](#), using components from the spare S2W that was part of the USS Nautilus program. All subsequent U.S. naval reactors have been PWRs.

Skipjack class

After Nautilus came the first of the Skipjack class of attack submarines. Skipjack's keel was laid down on 29 May 1956 by the Electric Boat Division of the General Dynamics Corporation in [Groton, Connecticut](#). Skipjack was launched on 26 May 1958 and commissioned on 15 April 1959. The new class introduced the teardrop hull and the S5W reactor to U.S. nuclear submarines. The Skipjacks were the fastest U.S. nuclear submarines until the [Los Angeles-class submarines](#), the first of which entered service in 1974.

Later classes of submarines

Next came the George Washington class Ballistic Missile submarines; the first was launched in June 1959 and commissioned in December 1959 (The US also later added some SSGNs, carrying guided missiles.). The largest submarines in the US Navy, USS Ohio class, are the first Trident ballistic missile submarines, commissioned beginning in 1981. The latest three submarines of this class are USS South Dakota (SSN 790, commissioned in February 2019), USS Delaware (SSN-791, commissioned in April 2020) and USS Vermont (SSN-792, commissioned in April 2020).

Aircraft carriers

USS Enterprise was the first [nuclear-powered](#) aircraft carrier and its keel was laid in 1958. It was launched in September 1960 and commissioned in November 1961. She was deactivated on 1 December 2012, and officially decommissioned on 3 February 2017. Enterprise is also the only aircraft carrier to house more than two nuclear reactors, having an eight-reactor propulsion design.

The Nimitz class is a class of 10 nuclear reactor-powered aircraft carriers in service with the United States Navy. The lead ship of the class was commissioned in May 1975, and the tenth and last of the class was commissioned in January 2009.

Ford-Class is a class of aircraft carriers being built to replace USS Enterprise and eventually the United States Navy's existing Nimitz-class carriers.

Soviet Union/Russian Federation

The important questions for the West in the early 1950s were about the capability of Soviet Union. Was the Soviet Union technically capable of producing an atomic powered submarine? If so, had the Soviet Navy the background and experience and would they

make good use of it? Was the Soviet Union capable of waging effective anti-submarine warfare against atomic powered submarines of the West such as the “Nautilus?” The first question was partially answered a few months after the launch of “Nautilus” when it was announced that the Soviets had built and successfully operated the world’s first peace time atomic power reactor in Obninsk. The significance of this announcement was the fact that, after successfully developing the atomic powered reactor, the Soviets had crossed the most difficult hurdle in building an atomic powered submarine.

Submarines

The Soviet Union soon followed the U.S. in developing nuclear-powered submarines in the 1950s. Stimulated by the U.S. development of the Nautilus, Soviet work on nuclear propulsion reactors began in the early 1950s at the Institute of Physics and Power Engineering in Obninsk, under Anatoliy P. Alexandrov, later to become head of the Kurchatov Institute. In 1956, the first Soviet propulsion reactor designed by his team began operational tests. Meanwhile, a design team under Vladimir N. Peregudov worked on the vessel that would house the reactor. After overcoming many obstacles, including steam generation problems, radiation leaks, and other difficulties, the first nuclear submarine, Leninsky Komosomol, entered service in the Soviet Navy in 1958. The submarine was built in Molotovsk, launched on 9 August 1957 after being commissioned in July 1958. It used a water cooled reactor (Anand et al., 2016).

During the construction of the Leninsky Komosomol, the first November-class submarine, the Soviet Union was also building liquid-metal cooled submarine propulsion systems. The liquid metal used by the Soviets/Russians was lead-bismuth eutectic (rather than the sodium tried by the US Naval Program). This technology was developed at the Institute of Physics and Power Engineering (IPPE) in Obninsk and used in two submarine classes: Project 645, a class in itself, and the Alfa class. Using liquid metal coolant was considered to have several advantages. It is more compact than PWRs since it needs no moderator. No heavy pressure vessel is needed; it operates at higher temperatures and, therefore, has a higher thermal efficiency than water cooled reactors. Additionally, lead-bismuth is not chemically reactive with water as is sodium. Refueling is faster, since the core is removed in a single operation, but was more frequent than in the US submarines. However, there are disadvantages: the melting point of the coolant is above room temperature, so the primary system must be kept heated at all times for the coolant to remain liquid. If not, the coolant will solidify and cooling will be interrupted. The liquid metal coolant will gradually oxidize and the oxides have to be removed regularly to avoid blockage of the coolant flow through the core. The LMC reactor was first used in 1962 in a special version of a November-class submarine (Project 645, K-27), which used two RM-1 reactors with capacity of 73 MWth each. At the height of the Cold War, approximately 5–10 nuclear submarines were being commissioned from each of the four Soviet submarine yards. From the late 1950s through the end of 1997, the Soviet Union, and later Russia, built a total of 245 nuclear submarines, more than all other nations combined. They even built submarines with a titanium hull, which came as a big surprise to the US and other nations. Soviet designated Project 661 was the Soviet Navy’s nuclear-powered cruise missile submarine and the only submarine of that design. It was the world’s fastest submarine and the first submarine ever constructed with a titanium hull. The boat is best known in the West by its NATO reporting name Papa class.

The Yankee-class nuclear submarines were the first of Soviet ballistic missile submarines (SSBN) to have thermonuclear fire-power comparable with that of their American and British Polaris submarine counterparts. The Yankee class was quieter in the ocean than were their Hotel-class predecessors, and had better streamlining that improved their underwater performance. These boats were all armed with six submarine-launched ballistic missiles (SLBM) with multiple nuclear warheads as nuclear deterrents during the Cold War. The new Yasen Class is projected to replace the Russian Navy’s current Soviet-era nuclear attack submarines. Fig. 4 shows a Typical Block Type propulsion system used in Soviet/Russian submarines and ice breakers.

Icebreakers

At the same time, the Soviet Union started work on “nuclear propulsion” for ice breakers. A nuclear-powered icebreaker is a nuclear-powered ship built for use in iced waters. Nuclear-powered icebreakers are much more powerful (35–60 MW_{shaft}) than their diesel powered counterparts (< 25 MW_{shaft}). Although nuclear propulsion is expensive to install and maintain, very heavy fuel demands, the need to clear ice for their fuel tankers, and limitations on range can make diesel vessels less practical and economical, overall, for ice-breaking duties. During winters, ice along the Northern Sea Route varies in thickness from 1.2 to 2.0 m and in central parts of the Arctic Ocean is 2.5 m thick on average. Nuclear-powered icebreakers can force through this ice at speeds up to 10 knots and in ice-free waters the maximum speed of the nuclear-powered icebreakers is as much as 21 knots. All eight of the Russian nuclear icebreakers have steam turbine—electric drive trains (AKER, 2016).

The first nuclear powered ice breaker was named “Lenin.” At its launch in 1957, the icebreaker NS Lenin was both the world’s first nuclear-powered surface ship and the first nuclear-powered civilian vessel. The Lenin was put into regular operation in 1959. Nuclear-powered icebreakers have only been constructed by the USSR (and later, Russia), primarily to aid shipping along the Northern Sea Routes in the frozen Arctic waterways north of Siberia. In all, 10 civilian nuclear-powered vessels have been built in the USSR and Russia. Nine of these are icebreakers, and one (Sevmorput) is a container ship with an icebreaking bow. The icebreakers have also been used for a number of scientific expeditions in the Arctic. Since 1989 nuclear-powered icebreakers have also been used for carrying tourists to the North Pole. TASS also reported in July 2019 that Russia hopes to build its first nuclear-powered aircraft carrier.

Fig. 4 Typical Block Type propulsion reactor used in Soviet/Russian submarines and ice breakers. <https://aris.iaea.org/PDF/KLT-40S.pdf>. This image is taken as reference only from IAEA technical document on KLT-40S.

United Kingdom

The Royal Navy had been researching designs for nuclear propulsion plants since 1946, but this work was suspended indefinitely in October 1952. The UK's Naval Nuclear Propulsion Program, NNPP, is closely tied to the US. The US supplied the UK with its first naval nuclear reactor and has supplied fissile material for core fabrication. US assistance to the UK NNPP has been part of a wider program of military nuclear cooperation that dates back to the 1940s Manhattan project. Cooperation abruptly ended in 1946 when the US Congress passed the Atomic Energy Act that severely limited the transfer of restricted nuclear information and materials to any other state, causing a major rift with its wartime ally in London. Negotiations to reestablish exchange of military atomic defense information, materials and technology began after an independent UK nuclear weapons program tested its first atom bomb in 1952 and hydrogen bomb in 1957; the United States agreed to supply the UK with one complete submarine nuclear reactor plant. Surprisingly, every country made a nuclear weapon before making nuclear reactors for propulsion. This enabled the UK to deploy its first nuclear-powered submarine, HMS Dreadnought, several years earlier than originally envisaged. It was launched in 1960 and commissioned into service in 1963. On 3 March 1971, Dreadnought became the first British submarine to surface at the North Pole. In 1973 it took part in the Royal Navy's first annual Group Deployment, when a group of warships and auxiliaries would undertake a long deployment to maintain fighting efficiency and "show the flag" around the world. The Royal Navy Submarine Service operates seven fleet submarines (SSNs), of the Trafalgar and Astute classes, and four ballistic missile submarines (SSBN), of the Vanguard class. The UK's first indigenous plant and core based on the S5W Westinghouse design was built by Rolls Royce and deployed on the attack submarine HMS Valiant in 1966. The current PWR2 core design, "Core H," has been designed to last the lifetime of the submarine (25–30 years), thereby eliminating costly mid-life reactor refueling. Core H fuels the new Astute-class SSNs and the four Vanguard-class SSBNs were fitted with the core during their long overhaul and refueling refits between 2002 and 2012 (Ritchie, 2015).

The UK has also been dependent upon the US for special nuclear materials (highly enriched uranium and plutonium) and tritium gas for its nuclear warhead. A total force of seven astute class fleet submarines is planned. As of April 2016, the first three boats are in commission and in service, while boats four to six are in various stages of construction. HMS Ambush, the Royal Navy's newest nuclear attack submarine, is one of the most sophisticated and powerful vessels of its type ever built.

France

The Q 244 project that started in 1955 was the first French attempt to build a nuclear propulsion reactor (Marie-Josée, 1996, Fribourg). The technology would be what was known best and could realistically be achieved with what was available: natural uranium and heavy water. This would require a submarine larger than the largest developed at the time. The project was abandoned in 1958 and France turned to the US for help (GOLDSCHMIDT, 1962; CEA, 2021; Histoire, 2021; LeFebvre, 2002). Of their wish list, the French delegation only obtained 20 t of enriched uranium, in spite of strong opposition from the US's Admiral Rickover. When asked during a Congress hearing if there was any chance that France would succeed in developing a propulsion reactor, the Admiral replied "not the slightest," from which it was concluded that the supply agreement could be signed. One of the conditions was that the enriched uranium would only be used for a research reactor on the land.

Submarines

The first nuclear propulsion reactor was built in the new nuclear research center of Cadarache, 70 km north of Marseille, destined to be the new test bench of the CEA, Commissariat à l'Énergie Atomique, for various advanced nuclear technologies. Since the agreement with the Americans excluded any technology transfer, the small Groupe de Propulsion Nucléaire (GPN) started from scratch and miniaturized the components of the reactor. In September 1959, the GPN received requirements from the Navy: a concise one-page document accompanied by a request to receive the preliminary project document 2 months later to build a submarine on land. The Prototype on Land (prototype a terre, PAT) used pressurized water and the enriched uranium from the United States which would allow a more compact reactor (André, 2021).

The first uranium enrichment plant started in Pierrelatte. France was now independent for its supply of enriched uranium. The PAT was the model for the first six SSBNs. The first was *Redoutable*, laid down in 1964, launched in 1967 and commissioned in 1971. The sixth, *Inflexible*, was laid down in 1980, launched in 1982 and commissioned in 1985.

The Navy being satisfied with the first SSBNs in operation, the time had come to build attack submarines; the construction of a new prototype on land started in Cadarache in 1970. A major innovation was introduced: the steam generator was placed directly above the core of the reactor. The primary block was very compact, resulting in a massive weight reduction from 700 to 400 t. Up to a significant power, the coolant was naturally circulating and thus completely silent. At higher speed the reactor was still silent, as only low-power pumps were required. Based on the experience of this land-based plant, six *Rubies class* were commissioned, the first in 1983 and the sixth in 1993. Unfortunately, the noise levels turned out to be higher than expected and a silencing program needed to be incorporated for the fifth, *Amethyste*, and the sixth, *Perle*. The first four boats were also modified to the same standard.

In the early 1980s the French Navy planned to replace the first generation of SSBN by boats that would be much more silent but also replace the ageing aircraft carriers with a nuclear aircraft carrier. K15 PWR concept was suggested; that would be almost the same for both applications and would draw on the previous successes. Starting in 1984, a near total overhaul of the CAP (Chaudier Avancée Prototype) was undertaken in Cadarache. The construction of *Le Triomphant* started in June 1989, launched in 1994 and entered active service in 1997. The submarine displaces 14,335 t, its speed is approximately 25 knots and maximum depth is 400 m (ARCEA GASN, 2010; Delaeter, 1999). Most of all, it produces approximately one thousandth of the detectable noise as compared to *Le Redoutable class* boats and is 10 times more sensitive in detecting other submarines. *Le Téméraire*, *Le Vigilant* and *Le Terrible* followed *Le Triomphant*. These are the most expensive submarines. The Barracuda program to replace the *Rubis class*, was started in 2006, the first of its class, *Suffren* was laid down in 2007, was launched in July 2019 and expected to be commissioned in 2020 (Marine, 2013).

Aircraft carrier

The aircraft carrier *Charles de Gaulle* was commissioned in 2001 and is equipped with two K15 reactors and four diesel-electric engines developing 40,230 HP each, driving two propeller shafts. With a speed of 27 knots, the *de Gaulle* fields the powerful naval variant of the Dassault Rafale and can also house a variety of other specialized aircraft and helicopters as needed (Jean, 2006).

China

The first Chinese nuclear-powered submarine, Han class, was laid down in 1967 but not completed until 1974. China became the first Asian country and fifth nation in the world after the United States, USSR, United Kingdom and France to build a nuclear propelled submarine. Throughout the 1950s and early 1960s the Soviet Union provided assistance to the People's Liberation Army Navy (PLAN), in the form of naval advisers and export of equipment and technology. A new class of submarine has been in development since the 1980s, when the PLAN first sought a replacement for the Han-class. Type 093 Shang class are believed to have some Russian influence.

The news item in CHINADAILY in April 2016 says that China is planning to build about 20 floating reactor platforms to meet the demand of maritime atomic propulsion. There have been rumors and speculation that China would also switch to nuclear-powered carriers (China Daily, 2016).

India

Although paper studies were ongoing for a number of years, actual work on the land-based prototype started in 1984, to be built in the Atomic Energy complex at Kalpakkam in the state of Tamil Nadu (Anand et al., 2016).

Discussions were held between India and the USSR about possible cooperation and technical support for the nuclear propulsion program. After extensive negotiations, the agreement was concluded in April 1982, conforming to the Nuclear Proliferation Treaty (NPT) and Missile Technology Control Regime (MTCR). The issue of detail design assistance on the reactor was omitted. For gaining operation and maintenance experience, the Soviet Union would lease a nuclear propelled submarine to the Indian Navy before induction of its own nuclear propelled submarine. Physical access to the submarine and its propulsion plant to the designers would be permitted to familiarize them with the layout and space constraints. A new management structure was evolved to design and build a land-based prototype propulsion plant and to design and build future nuclear submarines which included the Navy, DRDO (Defense Research Development Organization), and DAE (Department of Atomic Energy) personnel, similar to the one chosen by the US in late 1940s. The land-based reactor became critical on November 11, 2003 (Anand et al., 2016).

The submarine Arihant was launched in 2009 and underwent 7 years of testing and sea trials before being commissioned in August 2016. On November 4, 2018, the Indian Prime Minister Shri Narendra Modi announced that the Arihant, which means “Slayer of Enemies” in Sanskrit, the Indian Navy’s first domestically-built nuclear-powered submarine, completed Arihant’s first deterrence patrol. Thus, India became the sixth nation to build nuclear powered submarines.

India has already launched a second Arihant-class submarine, the Arihant which is expected to be commissioned soon. Two more of the same class are being built/planned. The Indian Navy is planning to build six nuclear attack submarines, as reported by the press in December 2019.

Brazil

Brazil’s nuclear submarine is being built with French assistance (DCNS, 2010), except for the nuclear reactor and associated uranium fuel-cycle technology, which is being developed by the Brazilian Navy (Acordo, 2008a,b; BBC, 2006; Jobim, 2007; PRO-SUB, 2010). According to open sources, the Brazilian Nuclear Submarine Álvaro Alberto (SN 10), which would be the first of six planned nuclear submarines, would run on a 48–50 MWth reactor. These submarines are a modified version of the Scorpene class diesel-powered submarine (Scorpene 2008, 2010; CORRÊA, 2010; Hecht, 2011; Sarkozy, 2009). While the first four are conventional subs, the fifth will place Brazil in the club of only six nations with nuclear-powered submarines. The program has been delayed by budget cuts and corruption scandals; the launch date of the first submarines has been pushed back until 2029 (Lorient, 2010; de Eliézer Rizzo, 2005).

Present day characteristics

Longer Core life

For the present-day propulsion plants, the effort is to design cores to last the life span of the plant and avoid periodic refueling. One of the main reactor core design challenges is to develop an efficient reactivity control system. Generally, traditional PWRs use a combination of three methods of reactivity control: moveable control rods, burnable neutron absorbers, and soluble neutron absorbers. Earlier, excess reactivity during start-up, due to higher enrichment, was controlled by a soluble poison like Boron in the coolant and/or by using Gadolinium oxide powder mixed with the fuel. This could increase the interval between refueling; the fission gas pressure inside fuel elements was one of the limitations to longer cycles, in addition to corrosion of the cladding. Neutronic investigation of alternative and composite burnable poisons is ongoing, such that the cores can last the lifespan of the plant. In addition to increasing the thickness of the cladding, new material like ZrB₂ is being investigated; the burnable poisons being investigated are Pu 240 or Am 241, mixed homogeneously with the fuel. Only the Russians use lead bismuth alloy as coolant in the fast reactors deployed in some of the submarines.

Quiet operation

The effectiveness of the present-day submarine depends upon its ability to remain undetected for long periods of time while it searches, tracks, or attacks from under the sea. This medium of concealment, however, is advantageous to the submarine only so long as it is not detected or deprived of its ability to detect. Before a submarine can be attacked, it must be detected, and its subsequent positions determined within the requirements of the available weapons system. Detection and position fixing can take place in two ways; there may either be some radiation or reflection of energy from the submarine to the searcher, or else the submarine may disturb one of the natural, static, spatial fields, such as the earth’s magnetic field, and betray its presence. Acoustic energy, while lacking the propagation speed of electromagnetic waves, is capable of being transmitted through sea to distances that are operationally significant and is thus the physical phenomenon used for antisubmarine warfare, underwater communications, and underwater navigation. The optimum use of sound requires a thorough understanding of its limitations so that these effects can be minimized. For example, sea water is not uniform in pressure, temperature, or salinity and all these characteristics have important effects on sound propagation through the sea. The requirement for predicting these effects on sonar performance has become a necessity.

In the nuclear propulsion plant, the cooling water pumps and steam turbines are the main source of noise; these two are absent in diesel electric propulsion, thus diesel electric boats are relatively silent. All effort is focused now to reduce noise levels. Up to a significant power, the coolant was naturally circulating and thus totally silent. At higher speed the reactor is still very quiet, as only low-power pumps are required and the steam generator block filters the noise. The evolution of detection methods implied further reducing acoustic signatures to much lower levels.

Increased electrification of on board services

According to the US Navy's Electric Ships Office (ESO), established in 2007 to develop and provide new types of power capabilities; integrated power and energy systems (IPES) will play an increasingly important role in tomorrow's fleets. Warship designers until now have used hydraulics, pressurized air, and steam to move large masses, such as aircraft catapults, aircraft elevators, and ship propulsion systems, yet new advances in high-power electronic devices may lead to all-electric power aboard surface vessels, even the most demanding systems, such as propulsion and catapults aboard aircraft carriers.

The electromagnetic aircraft launch system (EMALS)

This is an aircraft launching system developed by General Atomics for the United States Navy, to replace the steam catapults. The system employs a linear induction motor rather than the conventional steam piston. EMALS was first installed on the United States Navy's Gerald R. Ford-class aircraft carrier. Its main advantage is that it accelerates aircraft more smoothly with less stress on airframes. Compared to steam catapults, EMALS also weighs less, is expected to be economical, low on maintenance, and can launch both heavy and light aircraft, contrasted to a steam piston-driven system. It also reduces the carrier's requirement of fresh water, thus reducing the demand for energy-intensive desalination. During an aircraft launch, the induction motor requires a large surge of electric power that exceeds what the ship's own continuous power source can provide. As of 1994, the EMALS energy-storage system design accommodates this by drawing power from the ship during its 45-s recharge period and storing the energy kinetically using the rotors of four disk alternators; the system then releases that energy in 2–3 s. In 2015, the first full speed ship-board tests were conducted. In 2017, this catapult launch trial was conducted on the USS Gerald Ford.

AZIPOD® (Azimuthing Podded Drive) propulsion system

This is the electrically driven propulsion with an AC motor incorporated in a streamlined azimuthing pod unit directly driving a fixed-pitch propeller. The motor is controlled by a frequency converter, which produces full nominal torque in either direction over the entire speed range, including standstill. Each Azipod propulsion system is individually designed and optimized to achieve maximum performance. The name "Azipod" is a registered trademark of ASEA Brown Boveri (AZIPOD, 2021) Figs. 5 and 6 show the AZIPOD®.

This is a gearless steerable propulsion system where the electric drive motor is in a submerged pod outside the ship hull. The propeller is a fixed pitch type where the propeller speed is controlled. This design does not need rudders, long shaft lines, or stern transversal thrusters. Direct seawater cooling makes it possible to reduce the motor diameter; a compact motor and pod dimensions lead to a slimmer body and better hydrodynamics.

If the propellers are electrically driven, the motors can be designed for the propeller rotational speed and power can be transferred from one train to another. In addition, since the rotating mass connected to the propellers is considerably smaller, electric drive is less vulnerable to ice or other debris in the water.

Nuclear propulsion of commercial vessels

Worldwide, only four nuclear-power merchant ships have been built since the 1950s and only one is still in operation. These four ships, the *NS ("Nuclear Ship") Savannah* (US), the *Otto Hahn* (Germany), the *Mutsu* (Japan) and the *Sevmorput* (USSR/Russia), were built as demonstration projects and to showcase each nation's technical prowess. All four were considerably smaller than the 100,000–300,000 t vessels now in common use transporting bulk iron ore, coal and grain, as well as intermodal containers.

NS Savannah

The first nuclear-power merchant ship was the *NS Savannah*, designed during the late 1950s and launched July 21, 1959 at Camden, New Jersey (Savannah, 2020). The ship was a product of the US Atoms for Peace Program and included accommodations for 60 passengers as well as interior furnishings to display American design and household technology e.g., a dance floor, swimming pool, futuristic sculptures and a (water-cooled) Raytheon Radarange® microwave oven. The ship was a joint project of the US Atomic Energy Commission, Maritime Administration and Department of Commerce.

With a length of 181.7 m, a beam of 23.8 m and a maximum displacement of 19,800 t (cargo capacity 14,040 t), the ship's 15.1 MW_{shaft} PWR power plant could cruise at 39 km/h (21 knots) with a maximum speed of 44 km/h (24 knots). The range of the *NS Savannah* was 560,000 km on a single core load of 32 fuel elements.

The *NS Savannah*'s Babcock and Wilcox reactor used fuel with an average enrichment of 4.4% U-235 in 32 fuel elements forming a core 1.6 m in diameter and 1.7 m high and generating 74 MW_{th}. The reactor vessel was 5.2 m high, and the containment vessel

Fig. 6 Azimuthing Podded Drive (Front View). https://en.wikipedia.org/wiki/File:Mackinaw_WLBB-30_Azipod_thruster.jpg, https://en.wikipedia.org/wiki/File:First_Azipod.jpg. This is a work of the U.S. federal government, it is in the public domain in the United States. Public Domain Mark 1.0.

was 15 m high and 5 m in diameter and designed to withstand the 1.28 MPa pressure of a blow down from a loss of primary coolant.

After launching in 1959, the Savannah required another 30 months to complete installation and fueling of the reactor. Savannah began its maiden voyage August 20, 1962, first calling at Savannah, Georgia, its eponymous home port, and proceeding through the Panama Canal to Hawaii and ports on the West Coast. In 1964 Savannah visited Gulf and East Coast ports before crossing the Atlantic to call at European ports.

Passenger service was discontinued in 1965 and the ship was converted for all cargo use. At the same time the reactor was refueled after 3 years and 560,000 km of travel. Four of the 32 fuel elements were replaced and the other 28 were rearranged ("shuffled") to improve fuel usage. During its active use Savannah traveled 720,000 km (equivalent to 18 voyages around the earth), visited 32 domestic ports and 45 foreign ports, and was toured by 1.4 million people as part of the Atoms for Peace program. At the end of 1971, Savannah was deactivated and began a career as a museum ship, a role it performed at a pier in Baltimore harbor until

September [Savannah \(2019\)](#). The fuel was removed and the primary and secondary coolants, as well as activated internal components of the reactor, were removed. The reactor vessel itself remains in place.

The NS Savannah was a public relations and technical success, though there were operational problems which required the construction of a special service barge for on-site handling of contaminated coolant and the removal of radioactive fuel and core internals.

But Savannah could not compete economically as a cargo vessel. The stylish bow and placement of the superstructure and reactor amidships made the handling of cargo labor-intensive. The crew of 124 specially trained members was expensive. While the fuel and the reactor system performed well, at the time of inactivation in 1971 the price of oil was about \$3 per barrel. Later calculations indicated that an oil price of \$12 per barrel (a price that was doubled within the decade ([Macrotrends, 2020](#); [Inflation, 2008](#))) would have enabled Savannah to operate at a profit.

On September 19, 2019, Savannah was towed from Baltimore to Philadelphia where the U.S. Maritime Administration will keep the ship in “protective storage” for the near future, while planning for pre-decommissioning ([Chesapeake Bay Magazine, 2019](#)). The decommissioning must be completed by December 2031. NS Savannah is a National Historic Landmark ([Fig. 7](#)).

Otto Hahn

The Otto Hahn, named for the German discoverer of nuclear fission, was a trade and research vessel, whose keel was laid August 31, 1963 in Kiel and began service in October 1968. Its primary purpose was to test the feasibility nuclear marine propulsion. Having a length of 172 m, a beam of 23.4 m and a displacement of 17,141 t (standard), Hahn was slightly smaller but heavier than Savannah ([Hahn, 2009](#)). As a research vessel, the Otto Hahn had accommodations for 36 scientists, as well as a conference room and two laboratories.

Her 38 MW_{th} reactor and the steam turbine produced 8.09 MW_{shaft} for its single propeller at a speed of 17 knots. The PWR required fuel enriched to between 3.5% and 6% and contained fuel rods 830 mm long and 10.89 mm in diameter. The 1.7 t of fuel was arranged in 12 elements containing a total of 2810 rods. The lifetime of the core was 900 days at full power, resulting in an average burnup of 23 MW_{th}-d/kg. The primary coolant pressure was 8.3 MPa and outlet temperature was 300 °C. The three helical tube steam generators were inside the reactor vessel and had counter current primary and secondary flows, allowing for a superheat of 33 °C and 3 MPa at the steam outlet.

Otto Hahn was configured to carry passengers and ore. In 1972, after sailing 463,000 km in 4 years of operation, the reactor was refueled.

Fig. 7 NS Savannah. https://upload.wikimedia.org/wikipedia/commons/thumb/d/d7/NS_Savannah_exterior_MD2.jpg/2048px-NS_Savannah_exterior_MD2.jpg, this file is licensed under the Creative Commons Attribution-Share Alike 4.0 International license.

A major difficulty with continued operation of the Otto Hahn was the denial of permission to use the Panama and Suez canals and to visit many ports on a continuing basis. In 1979, after traveling under nuclear power 1.2 million km (equivalent to 30 times around the earth), the ship was deactivated and the reactor and steam turbine propulsion plant were replaced with a conventional Diesel engine.

In 1983, Otto Hahn was recommissioned and leased as the container ship Trophy. The ship served in commercial service under a series of different names until 2009 when it was scrapped at Alang, India.

Mutsu

Although the construction of the Mutsu was contemporaneous with the Savannah and Otto Hahn, the Mutsu had a delayed and controversial history (Mutsu, 2020). Nevertheless, the ship, minus its nuclear reactor, is still in service under another name today.

The Mutsu was ordered in November 1967, laid down in November 1968 and launched June 11, 1969. The reactor was completed on August 25, 1972 and fuel was loaded the following September. Mutsu's length is 130 m, beam 19 m and gross tonnage is 8240 t. The maximum thermal output of the reactor was 36 MW_{th}, producing 7.5 MW_{shaft} for propulsion at 32 km/h.

The original plan was to conduct initial nuclear tests at the pier in Ominato but protests from local fishermen forced a change in the testing site in the Pacific Ocean to 800 km east of Cape Shiriya. At the beginning of these tests on September 1, 1974, when the reactor was at 1.4% of full power, a neutron and gamma shielding deficiency was detected. The cause was streaming of radiation through gaps in the shielding. Westinghouse, in a review of the design, had warned of such a possibility, but the design was not changed. Although there was no significant radiation exposure, Mutsu was blocked from returning to port for 50 days. Later analysis of the situation pointed to the lack of coordination between the two contractors on the project and to conceptual mistakes in the shielding calculations.

From late 1974 until February 1991, Mutsu underwent a series of port changes, modifications and overhauls. Its original design objective was to complete 82,000 km under nuclear power. With that goal accomplished in 1992 Mutsu was decommissioned.

The reactor was removed from the Mutsu in 1995 and the vessel was decontaminated, then rebuilt as the ocean observation vessel RV Mirai, which remains in service today (Mirai, 2020).

Sevmorput

The most recent, and only currently-operating, nuclear commercial vessel is the Sevmorput (from Northern Sea Route—Severn Morskoy Put), whose design was begun by the Ministry of the Merchant Marine and the Ministry of Shipbuilding Industry of the Soviet Union in 1978. The keel was laid in 1982, launching was in 1986 and delivery was in 1988 (Sevmorput, 2020). The Sevmorput was designed to serve shallow ports in the Russian Arctic as an icebreaking LASH (lighter aboard ship) carrier. As such it had the capability of transport 74 shallow-draft barges ("lighters") weighing 300 t each and to on/off-board those lighters near the entrances to shallow ports along the Arctic coast. If it is not transporting lighters Sevmorput can carry 20- and 40-ft cargo containers with a total capacity of 1328 twenty-foot equivalent units (TEU). Its maximum displacement is 61,880 t and its maximum sum of cargo, fresh water and provisions is 33,980 t at maximum draft and 26,840 t when operating at reduced draft for icebreaking. The ship has a length of 260.3 m, a beam of 32.2 m and a maximum draft of 11.8 m (in summer). Therefore, it is about twice the length and three times the displacement of the Savannah.

Sevmorput's reactor is a KLT-40, having a thermal output of 135 MW, and using 150.7 kg of highly enriched uranium in the form of a uranium-zirconium alloy. The maximum power to the single propeller is 29.42 MW_{shaft} at a maximum speed of 20.8 knots (38.5 km/h). Unlike Russian nuclear icebreakers which have nuclear-turbo-electric drive trains, Sevmorput has a mechanically coupled steam turbine driving a single 6.7-m diameter propeller. It can also maintain a speed of 3.7 km/h in 1-m thick ice. The reactor has only been refueled twice since beginning operations in 1989.

Initially Sevmorput was not permitted to enter several of the Siberian ports which it was designed to serve because of popular protests and fears following the Chernobyl accident in 1986. The ship was mainly used on the Murmansk-Dudinka route and also made several voyages to Vietnam in the 1990s. In early 2020 it was reportedly preparing for a supply trip to the Russian research stations in Antarctica.

Future applications of nuclear propulsion

As described in the preceding section, four nuclear-powered cargo ships have been built since the late 1950s by four countries. They were designed as demonstration projects to gain experience in civilian marine propulsion using nuclear power. Generally, the reactors and power trains performed satisfactorily, though all spent more time in repair yards than comparable conventional cargo ships. The major economic issues were due the need for a larger number of highly trained crew members, the lack of public acceptance in some prospective ports and the limited number of locations where repairs and refueling can be conducted.

Very large container carriers

Conventional commercial shipping has also evolved. During the six decades since the *Savannah* was launched, large container ships have taken over almost all non-bulk cargo shipping. Very large low-speed diesel engines have been designed to operate at the propeller RPM, eliminating the need for large reduction gearing. Until recently, sulfur and carbon dioxide emissions from ocean-going vessels have not been an issue.

Among the largest of these recent ships are the Maersk Triple-E class, operated by the Danish firm A. P. Møller-Maersk. At the time the first of the class were delivered in 2013 they were the largest container ships in the world, capable of carrying 18,340 twenty-foot equivalent units (TEU). The 31 Triple-E ships were delivered in two generations, the first 20 between July 2013 and June 2015 and the second generation between April 2017 and January 2019. Their length is 399 m, beam 59 m and draft 16 m, with a maximum displacement of 251,000 t, more than 10 times the maximum displacement of the *Savannah*.

The two main diesel engines on Triple-E vessels produce 31 MW_{shaft} each at 73 RPM and are each coupled directly to a 9.8 m diameter four-bladed propeller. Designed cruising speed is 19 knots, slower than the 23–26 knots for other large container ships. Although these ships are capable of 25 knots, fuel consumption is reduced by about 42% at 19 knots. Cruising at 19 knots typically lengthens voyage times by 2–6 days.

High speed container ships

Beginning with the MV *Boston* in 2006, Maersk built seven “B-class” container ships, with capacities of 4196 TEU for high-speed service between China and the United States. These ships were capable of 68 km/h top speed and cruised at 54 km/h. At cruising-speed the engine power was about 60 MW_{shaft}. The B-class ships were designed to serve a market for cargo shipping faster than the standard container ships at 37 km/h but less expensive than airfreight. Because their fuel consumption was 300 t/day the B-Class ships proved to be uneconomic compared with the larger Maersk vessels in their E-Class and Triple E Class. The downturn in the world economy in 2008–10 meant that the vessels were never used on their intended route.

Very large bulk carriers

Large ships up 200,000–300,000 t carry commodities such as crude oil, coal, metal ores and grain on long oceanic routes. Because the commodities are not as time sensitive as container freight and to reduce fuel consumption, these bulk carriers cruise at 13.5–15 knots. Power requirements are about 15–20 MW_{shaft}, depending on displacement, propeller diameter and engine speed (MAN, 2018).

Atmospheric emissions of shipping

World seaborne trade in 2018 was 11 billion t (UNCTAD, 2018) and emitted 940 million t of carbon dioxide through the use of fossil fuels for propulsion. By comparison, in 2018 worldwide commercial aviation operations emitted 918 million t of carbon dioxide, 2.4% of all CO₂ emissions worldwide (Environmental Impact Aviation, 2020). Commercial aviation is currently under pressure to reduce their greenhouse gas emissions. Seaborne trade may soon face the same pressure.

Conclusion

The four commercial demonstration projects, *Savannah*, *Otto Hahn*, *Mutsu* and *Sevmorput*, showed that nuclear marine propulsion could be technically feasible although staffing and economic issues remain. During the last 50 years, the sizes of typical cargo vessels have increased by at least a factor of 10 and the propulsion power needed has increased to the 30–80 MW_{shaft} range.

During this time of low petroleum prices and little enthusiasm for reducing greenhouse gas emissions, rapid adoption of alternative power sources, particularly of nuclear power, is unlikely. Marine shipping is a very competitive industry and recent ships, such as the Triple-E Class, are finely tuned to the optimum operating point. Nevertheless, over the next 50 years, when the four demonstration ships will approach their centennial, worldwide trade will continue to grow, particularly as the economies of South Asia, Africa and South America develop. Seaborne trade will continue to be the most economical method for crossing oceans. If the many scientific models for global climate change are even approximately correct, there will be increased pressure to reduce Green-House Gas (GHG) emissions with the least impact on the world economy.

The power requirements for large container ships, bulk ore and grain carriers, and high-speed container ships are now in the same general range (30–80 MWe) as some of the small modular reactors (SMR) now being designed (Stanculescu, 2021; Ingersoll, 2021; Slaybaugh et al., 2021). Except for a return to sailing ships, there are no other options beyond small reactors for eliminating the GHG emissions of seaborne shipping. The operation and maintenance costs of SMRs could be dramatically reduced by using artificial intelligence based predictive maintenance and advanced control systems. SMRs can be designed to have inherent safety that will hopefully contribute to public acceptance. Nevertheless, careful design will be necessary in avoiding the public acceptance and economic problems faced by the early demonstration projects.

Introduction

Two of the critical subsystems required for any space mission are power and propulsion. Power enables the space system to operate; for example, sensors to function, computers to provide control, and communication equipment to transmit information to and from the space system. Propulsion enables the space system to reach its destination and to orient itself as needed to meet mission objectives (for example, moving into orbit, pointing sensors at the desired targets and pointing antennae for communication back to Earth).

Because of the mass, size and cost constraints on payloads launched from Earth it is very important to have the lowest mass and smallest payloads that can be reasonably built. That, in turn, means getting the highest performance out of every subsystem on the payload (or space system). Nuclear power and nuclear propulsion provide such high performance for a number of proposed missions beyond Earth orbit. The following sections will provide an introduction to nuclear power and nuclear propulsion for space systems. Subsequent chapters in Section 9 will provide additional information as shown in the list below.

Power sources

Fig. 1 provides some examples of the different ways of providing electrical power to a space system. Fig. 2 illustrates the various technologies in a diagrammatic form.

As illustrated in Fig. 2, most power sources depend upon some source of heat or, in the case of solar power, the “heat” comes in the form of light from the Sun.

Subsequent chapters in Section 9.0 will provide additional information on these conversion systems (e.g., Stirling convertors aka “linear oscillators” and improved radioisotope power source designs).

Types of Spacecraft Power

Fig. 1 Types of Spacecraft Power Sources. Source: NASA.

Fig. 2 Power source options for spacecraft. Source: NASA.

Historically, the conversion system of choice for space nuclear power systems (both radioisotope and reactor) has been thermoelectric, which is based on an effect discovered in 1821 by Thomas Johann Seebeck that an electric voltage is produced when two dissimilar metals (“legs”) are joined in a closed circuit and the two junctions are kept at different temperatures. Typically in these thermoelectric conversion systems, the material in the thermoelectric element is a semiconductor with one leg being “positive” and the other being “negative.”

Most space systems are “power hungry,” that is, they can use all of the power they can get. But space systems are also constrained by size (e.g., what will fit into the launch vehicle) and mass (e.g., how much the launch vehicle can carry). Nuclear power sources offer the advantage of providing lots of power in compact packages. This can be seen by considering that solar power or chemical power typically involves the release of electron volts (eV) of energy to create an electrical current whereas nuclear power sources release millions of electron volts of energy.

Fig. 3, which is drawn from U.S. Department of Energy and NASA studies, illustrates the qualitative regimes of space power sources in terms of power required and duration of the mission. In **Fig. 3**, the term “Nuclear Fission” refers to the use of the fissioning of a material (such as uranium-235) to produce heat that can then be converted into usable electric power. The term “Solar” refers to the use of solar cells on arrays to convert sunlight into usable electric power. The practicality of solar power is highly dependent on the application. The “Solar at Jupiter” region indicates the power level where solar power might be used under special orbital conditions (e.g., avoiding the Jovian radiation belts); noting that the power level would substantially smaller when further out in the solar system (note that the level of degradation will depend on radiation effects). The dashed lines on **Fig. 3** represent the power levels where solar power might be the most practical choice at other locations. The dashed line for “Moon or Mars surface” includes the effect of eclipses, dust storms, etc., but will vary by specific location and/or application. The term “Chemical” refers to the use of batteries or fuel cells to produce power (note that chemical systems have limited lifetimes; eventually they need to be recharged” using a power source such as nuclear or solar).

Both nuclear and solar power sources have been used on the same mission (for example, the early Transit Navy navigational satellites). And chemical energy (i.e., batteries) has been used to provide peak power on some nuclear and solar missions (such as the Viking Mars Landers).

In summary, nuclear power sources offer superior performance in those long-duration regimes where there is little or no sunlight (such as outer-planet missions) or where there are significant environmental threats (such as the radiation belts around Jupiter). (Chemical systems lack the lifetime to be the primary power source but they can supplement nuclear or solar power sources where more power is needed for short periods of time.) The long-duration performance can be seen with the RTGs of the two Voyager spacecraft which have been providing electrical power for over 43 years (cf. [Bennett, 2021](#)).

Nuclear power sources

As shown in **Fig. 2**, there are several ways in which heat energy can be converted into usable electrical energy. The heat from a radioisotope heat source or a nuclear reactor heat source may be converted into electrical energy by means of (1) dynamic conversion such as turbine-alternators (as is often done in terrestrial power plants) or linear alternators; or (2) by static conversion such as with thermoelectric elements, thermionic converters or thermophotovoltaic elements. To date, all U.S. space nuclear power sources that have been flown have used thermoelectric conversion.

Radioisotope power sources

Traditionally, radioisotope power sources (or, sometimes termed radioisotope power systems) have used static conversion (e.g., thermoelectric conversion) or (in ground experiments) dynamic conversion. Both types will be discussed in the next sections.

Fig. 3 Qualitative regimes of space power applicability. Source: U.S. DOE and NASA studies and David Poston studies.

Radioisotope thermoelectric generators (RTGs) (Bennett, 1995; Buden, 2011a; Corliss and Harvey, 1964)

Thermoelectric conversion is illustrated diagrammatically in Fig. 4 for a radioisotope thermoelectric generator (RTG). An RTG basically consists of two major components: the heat source (which contains the radioisotope fuel) and the converter (which converts the heat from the heat source into usable electrical power).

As shown in Fig. 4, Step 1, the radioisotope fuel decays spontaneously emitting particles that produce heat when the particles are absorbed in the materials of the RTG. All of the U.S. RTGs flown to date have used the radioisotope plutonium-238 (Pu-238 or ^{238}Pu) as the fuel. Plutonium-238 decays mostly by emitting alpha particles (essentially the nuclei of helium atoms). The alpha particles are absorbed in the heat source producing heat that can elevate the temperature over a range up to about 1300 K as needed by the converter. Fig. 5 shows a plutonium-238 oxide fuel pellet that has been self-heated through the use of an insulator causing it to glow in a darkened room. (Without such self-heating, the pellet would have a dull gray appearance.)

In Step 2, the heat is converted directly into electrical power by being absorbed in the thermoelectric elements. The electrical power is then sent to the spacecraft for management and distribution (Step 3).

While obviously an RTG must operate reliably or it won't be used, the first objective in designing and using an RTG is to ensure that it is safe, that is, that the fuel does not come in contact with humans. As noted earlier, size and mass are also critical—the smaller and lighter the better for space systems where every kilogram launched into space costs.

Thermoelectric conversion is based on the “thermoelectric effect” which was discovered in 1821 by Thomas Johann Seebeck. The idea of using the thermoelectric effect to produce electrical power from the heat of radioisotopes was developed by John Birden and Ken Jordan who were posthumously inducted in 2013 into the U.S. National Inventors Hall of Fame.

Fig. 4 How a radioisotope thermoelectric generator (RTG) works. Source: U.S. Atomic Energy Commission.

Fig. 5 Plutonium-238 oxide fuel pellet glowing after having self-heated. Source: Los Alamos National Laboratory.

Radioisotope dynamic power systems

The first U.S. radioisotope power source, termed SNAP-1 (for Systems for Nuclear Auxiliary Power One), used dynamic conversion. The objective of SNAP-1 (shown in Fig. 6) was to provide 500 watts of electrical power (We) for a 60-day mission.

The dynamic power conversion systems that have been studied (e.g., Brayton, Rankine, Stirling) operate through a changing magnetic field which induces a current in a conductor. The magnetic field can be changed by rotating a magnet (e.g., Brayton and Rankine) or by causing it to oscillate (e.g., Stirling). The induced current then becomes the source of electrical power. (The induced electromotive force associated with the electric current is a result of Faraday's Law.) Efficiencies in the order of 20–30% or more are possible (compare to the 5–10% efficiencies of thermoelectric conversion).

In the SNAP-1 concept, a heat source fueled with cerium-144 was to heat a mercury fluid, vaporizing it in the boiler and sending it through a miniature turbine-alternator system to produce 500 We of electrical power at an thermal-to-electric efficiency of about 9.4% which compared favorably to the (then) 5% efficiency of RTGs. (The program did not advance to the point of actually using cerium-244 which has a half-life of about 285 days and decays primarily by emitting beta particles (electrons)). The technical term for the conversion cycle is Rankine named after William Johnson Macquorn Rankine who studied the thermodynamic properties of steam. While the missions in the late 1950s did not require the high power of SNAP-1, a larger version of the mercury Rankine conversion system was used in the SNAP-2 space nuclear reactor.

In the 1970s, the Rankine technology was resurrected in the US for radioisotope power sources such as the Kilowatt Isotope Power System (KIPS), shown diagrammatically in Fig. 7. Instead of mercury, KIPS employed Dowtherm A (an organic eutectic mixture of biphenyl and biphenyl ether) as the working fluid to produce about 1400 We at a system efficiency of about 16.6%. The advantage of higher efficiency is that less of the expensive Pu-238 fuel is needed to produce the same electrical power and it may enable a lower mass radioisotope power source.

Fig. 6 SNAP-1 turbomachinery package with shaft assembly shown separately. Source: TRW and USAEC.

Fig. 7 Diagram of the Kilowatt Isotope Power System (KIPS) which used a Rankine cycle power conversion system. Source: U.S. Department of Energy.

Another dynamic conversion system that has been studied for both radioisotope and nuclear reactors is the Brayton system (named for George Brayton) which uses an all-gas working fluid with no liquid-to-vapor phase change. In tests run in the late 1970s under the Brayton Isotope Power System program a 25% thermal-to-electric conversion efficiency was demonstrated.

A third dynamic conversion option is the Stirling conversion cycle (named for Robert Stirling) which employs a linear oscillator. NASA has studied the Stirling conversion system for both radioisotope and reactor power sources.

Nuclear reactor power sources (Buden, 1994, 2011a; Voss, 1984)

For those missions requiring large amounts of power (10s of kilowatts and higher) and/or which will operate in a hostile environment (e.g., limited or no sunlight, high radiation fields, etc.), a nuclear reactor is a very competitive option, if not the only viable option. (In the same situation but for lower powers a radioisotope power source is competitive.) The overall concept of a nuclear reactor power source (shown diagrammatically in Fig. 8) is similar to that of radioisotope power sources, i.e., the reactor produces heat which is transmitted to a conversion system that converts the heat (often called thermal power) into usable electrical power. Unused or “waste” heat is rejected often by means of fins that allow the waste heat to be radiated to space. However, whereas the

Fig. 8 Diagram of a generic nuclear reactor power source showing the flow of heat from the nuclear reactor to the energy conversion device. Any heat not used to produce electricity is radiated away to space via the waste heat radiator. Source: U.S. Atomic Energy Commission.

radioisotope power source produces heat from the radioactive decay of the radioisotope fuel, the nuclear reactor produces heat from the fissioning (“splitting”) of the reactor “fuel” (typically uranium-235 which is also written as U-235 or ^{235}U).

While a radioisotope heat source produces a source of thermal power (which decays at a known rate) without human intervention, a nuclear reactor can produce a variable source of thermal power through the reactor control system. Under the SNAP reactor program, studies (either analytical or experimental) were undertaken on several conversion cycles: thermoelectric (e.g., SNAP-10 and SNAP-10A), Rankine (e.g., SNAP-2, SNAP-4 and SNAP-8), Brayton (e.g., SNAP-8, Advanced Hydride Reactors and the Advanced Liquid-Metal-Cooled Reactor) and thermionic (the in-core thermionic reactor). (Staub 1973; Voss 1984) Thermoelectric conversion was the choice for the U.S. SP-100 space nuclear reactor power system program. More recent studies have focused on using a Stirling conversion cycle. The reader is referred to Chapters 5 through 10 for more information on the reactor concepts and their conversion systems.

The U.S. has only launched one space nuclear reactor, the SNAP-10A reactor launched on 3 April 1965 to become the world’s first nuclear reactor space power system. The objective of the reactor flight test was to produce 500 We under automatic control in space. The reactor initially produced more than 600 We. After 43 days of successful operation, the reactor was shutdown as the result of a high voltage failure sequence in the electrical system of the Agena spacecraft. (A ground test twin operated successfully for over a year.) Fig. 8 shows a technician standing next to a SNAP-10A reactor (not operating with nuclear power!).

Fig. 9 illustrates the various elements of the SNAP-10A reactor and Fig. 10 is an artist’s concept of the SNAP-10A reactor with its Agena upper stage in orbit (Fig. 11).

The overall diagram of the SNAP-10A space reactor power system is illustrated in Fig. 12.

In the 1980s and early 1990s, the U.S. worked on the SP-100 space nuclear reactor power system illustrated as a flight module in Fig. 13.

More recently, NASA and the U.S. Department of Energy (DOE) have been studying a kilowatt-class nuclear reactor termed “Kilopower” which could be used to power a lunar base or a Mars base using Stirling conversion (see illustration in Fig. 14).

Separately, the former Soviet Union flew over 30 nuclear reactors, mostly to power radar ocean surveillance satellites.

Nuclear propulsion

Humanity depends on propulsion systems to send its scientific and human missions where they want to go. Like space power systems, it is extremely important that the propulsion system have high performance and low mass. Nuclear propulsion offers just such benefits thanks to the inherently high energy content of nuclear fission (the splitting of atomic nuclei). In this section two types of nuclear propulsion will be considered: nuclear thermal propulsion (NTP) and nuclear electric propulsion (NEP).

One of the key attributes of any propulsion system is its specific impulse, that is, the amount of impulse (measured in units of force/thrust multiplied by time and divided by the mass of the thruster). In the metric system, the units are meters per second (m/s). One can think of specific impulse as analogous to gas mileage in an automobile—the higher the specific impulse the better.

Nuclear thermal propulsion (NTP) (Bennett et al., 1994; Buden, 2011b; Bussard and DeLauer, 1965; Dewar, 2004)

Chemical rockets, which have launched most of humanity’s payloads to date, operate by creating a hot gas through a chemical reaction and then expelling that hot gas out of the nozzle of the rocket engine. This usually means carrying two chemical propellants: the fuel which “burns” and the oxidizer that allows the fuel to “burn”. The nuclear thermal rocket replaces the two chemical propellants with one propellant that is heated by a nuclear reactor as illustrated in Fig. 15.

In principle, a nuclear rocket can produce a specific impulse twice that of a chemical propulsion system (and maybe more than that). This translates into a greatly reduced mass that must be carried into low-Earth orbit (LEO) for human missions to the Moon and Mars. Beginning in the mid 1950s through the 1960s, the U.S. tested some 20 reactors as part of its Rover/NERVA program (see Chapters 11–12). (NERVA is an acronym for Nuclear Engine for Rocket Vehicle Applications.) Fig. 16 shows a comparison of the NERVA reactor with a human.

Fig. 17 is an artist's illustration of a nuclear thermal rocket orbiting over Mars.

NASA, in cooperation with the U.S. Department of Energy, is continuing to study nuclear thermal propulsion for human missions to Mars and the Moon (see Chapters 13 and 14).

Nuclear electric propulsion (NEP)

Nuclear electric propulsion (NEP) is another way of utilizing the high performance of nuclear reactors to move spacecraft. Instead of heating a propellant (such as hydrogen), the nuclear reactor would provide electrical power to electric thrusters which would

Fig. 13 SP-100 space reactor power system module. The nuclear reactor is shown at the left near the thermoelectric power converters. The mission module is shown at the right and attached to the reactor by means of a separation boom which helps reduce the nuclear radiation. MUX, Multiplexer; TEM, Thermoelectric ElectroMagnetic. Fig. 14 Artist's concept of Kilopower nuclear reactors on Mars. The nuclear reactor and the Stirling conversion subsystem are shown at the base while the radiator is shown as a flat disk at the top. Source: NASA.

provide the propulsive force. In short, this is basically combining the space nuclear reactor technology discussed earlier with electric propulsion (see Chapter 14). A conceptual schematic of an NEP vehicle is shown in Fig. 18.

Studies of NEP have considered a range of electric thrusters such as ion engines, Hall-effect thrusters and magnetoplasmadynamic (MPD) thrusters. In a sense, NEP has already been flown—the SNAP-10A reactor flight test described earlier included an ion thruster that was operated briefly. (Chapter 15 provides more information on nuclear electric propulsion.)

Fig. 15 Diagram of a nuclear thermal rocket (NTR). Liquid hydrogen is pumped from the tank on the right into the nuclear reactor where it is heated and then expelled through the nozzle. Since a nuclear rocket only needs one propellant (unlike chemical propulsion systems which need two) the mass of the ejected hydrogen propellant is less and the velocity of the hydrogen is much higher. Source: NASA and U.S. Atomic Energy Commission.

Fig. 16 NERVA mockup. (NERVA stands for Nuclear Engine for Rocket Vehicle Applications.) Source: Aerojet Nuclear Systems Company.

In theory, larger versions of NEP vehicles with much more power could be designed, large enough to permit cargo and human missions to Mars. Because of the low thrust of electric propulsion thrusters, the NEP vehicle would have to spiral away from Earth (no direct transfer such as with nuclear rockets or chemical rockets) but once the NEP vehicle has reached escape velocity in principle the transit time to Mars can be approximately equivalent to the higher thrust options. The advantage of NEP is that the electric thrusters have very high specific impulses, perhaps 10–20 times that of chemical rockets; hence, NEP offers a very fuel efficient method of transportation.

Fig. 19 shows an artist's concept of a nuclear electric propulsion spacecraft going to Mars.

Concluding remarks

Both nuclear power and nuclear propulsion have strong technical bases thanks to years of study and experiment. Both technologies address the critical need for energy-rich power and propulsion.

Introduction

Radioisotope power systems provide electrical power or thermal power by using the natural radioactive decay of certain isotopes. These isotopes are unstable in the sense that they emit radiation; hence they are termed “radioisotopes” (Previtali, 2021). Typically the radiations emitted may be alpha particles (nuclei of helium atoms), beta particles (electrons) or gamma rays (high energy packets of energy). In certain cases (such as spontaneous fission), neutrons may be emitted.

The different radiations emitted vary in their capability to penetrate materials. For example, alpha particles are easily stopped such as with sheets of paper. Beta particles can penetrate more material and gamma rays are typically the most penetrating of the three. Ideally, for a radioisotope power source, the radiation emitted should be contained within the power source itself and therefore gamma-emitting radioisotopes are not generally used for space RTGs. Table 1 lists some radioisotope fuels.

Mission and power designers in the U.S. have historically selected plutonium-238 as their preferred radioisotope. More recently, European researchers have been investigating americium-241.

An important criterion in selecting a radioisotope for power is what is termed its half-life, that is, the time it takes for the radioisotope to decay to half of its original amount of radioactivity. For long-lived space missions (such as the two Voyager spacecraft which have operated for more than 43 years), the longer the half-life the better.

The long half-life of plutonium-238 has enabled the two Voyager spacecraft to complete their planetary missions (first spacecraft to visit Jupiter, Saturn, Uranus and Neptune) and to enter interstellar space (on 25 August 2012 for Voyager 1 and on 05 November 2018 for Voyager 2). With the benefit of long-lived radioisotope power, the Voyager spacecraft have become humanity’s envoys to the stars. Fig. 1 is an artist’s concept of Voyager 1 in interstellar space.

Fig. 2 illustrates diagrammatically the radioactive decay of the radioisotope plutonium-238.

When the emitted radiation is absorbed in the material of the radioisotope power source, heat is released. That heat can be used to power a conversion system that converts heat to electrical power analogous to the way terrestrial power plants use a source of heat (e.g., coal, gas, nuclear) and a thermal-to-electric conversion system to produce electrical power. Fig. 3 illustrates the thermal power by showing a ~ 63-watt plutonium-238 oxide fuel pellet that has been allowed to self-heat by insulating it to drive the temperature up to hundreds of degrees kelvin then removing the insulation while viewing the pellet in a darkened room.

For the types of radioisotope power sources that have been studied and/or used in space missions, there are two principal types of thermal-to-electric power conversion: static (“direct”) and dynamic. In the static conversion systems there are no moving parts, i.e., the thermal power (heat) is directly converted into electrical power. For dynamic conversion systems, moving parts such as turbine-alternators or linear alternators are employed to produce the electrical power (similar to what happens in terrestrial power plants).

*NASA retired.

Table 1 Some candidate radioisotope fuels.

Radioisotope fuel	Half-life (years)	Initial power density (100% basis) (watts/g)	Major radiations
Americium-241	432.2	~0.1	Alpha
Cobalt-60	5.24	17.8	Gamma, beta
Strontium-90	28.6	0.933	Beta, gamma, bremsstrahlung
Polonium-210	0.38	144	Alpha
Plutonium-238	87.6	0.56	Alpha
Curium-244	18.1	13	Alpha

**Fig. 1** Voyager 1 spacecraft entering interstellar space. Courtesy of Artist's conception, NASA/JPL.**Fig. 2** Diagram of the radioactive decay of plutonium-238 which has a half-life of approximately 87.7 years. Courtesy of U.S. Atomic Energy Commission.

Radioisotope thermoelectric generators (RTGs) (Buden, 2011; Cataldo and Bennett, 2011; Corliss and Harvey, 1964; Corliss and Mead, 1971)

With one exception, all the nuclear-powered U.S. spacecraft have used radioisotope thermoelectric generators (RTGs). As shown in Fig. 4, an RTG consists of two basic elements: (1) a radioisotope heat source (which, as its name suggests, produces heat from the absorption of the radiation emitted by the radioisotope) and (2) the converter which directly converts the heat into usable electrical power.

In all the U.S. RTG-powered spacecraft flown to date, the radioisotope used to produce the heat is plutonium-238, which has a half-life of 87.7 years. This is sufficiently long for long-duration space missions such as the two Voyager spacecraft which were launched in 1977 and are still operating after having made flybys of Jupiter, Saturn, Uranus and Neptune. The primary radiations emitted by plutonium-238 are alpha particles which are largely absorbed in the heat source itself thereby producing the heat.

Fig. 3 Self-heating of the fuel pellet for the General-Purpose Heat Source. Radioisotope Thermoelectric Generator (GPHS-RTG). The GPHS-RTG contains 72 of these fuel pellets. (The pellet is ~ 27.5 mm in diameter and 27.6 mm in length. The mass of a pellet is ~ 151 g.)

Fig. 4 Diagram of a radioisotope thermoelectric generator (RTG). Courtesy of U.S. Atomic Energy Commission.

Production of plutonium-238 begins at the U.S. Department of Energy's Idaho National Laboratory (INL), which stores the existing inventory of neptunium-237 feedstock and ships it as needed to the U.S. Department of Energy's Oak Ridge National Laboratory (ORNL). Engineers mix the neptunium oxide with aluminum and press the mixture into high-density pellets. They use the High Flux Isotope Reactor, a DOE Office of Science User Facility at ORNL, to irradiate the pellets, creating neptunium-238, which quickly decays and becomes plutonium-238. The plutonium radioisotope fuel is on the order of 84% plutonium-238 with the rest of the plutonium mostly plutonium-239.

The irradiated pellets are then dissolved and ORNL staff use a chemical process to separate the plutonium from remaining neptunium. The plutonium product is converted to an oxide and shipped to DOE's Los Alamos National Laboratory, where the material will be stored until needed for a mission. Remaining neptunium is recycled into new targets to produce more plutonium-238.

In an RTG, the heat from the decay of the radioisotope is transmitted to the converter by conduction (direct contact) or radiation (similar to the heat one feels from a fireplace). The converter in an RTG consists of many thermoelectric elements which operate on principles similar to the thermocouples that have been used to measure temperature. The thermoelectric element consists of a "hot shoe" which directly absorbs the heat and a "cold shoe" which radiates any unused heat into space (see Fig. 5). The principle is derived from that discovered by Thomas Johann Seebeck more than 200 years ago: if two dissimilar metals are connected at two junctions, one hotter than the other, there will be an electrical voltage (hence a current) produced. Efficiencies of thermoelectric conversion have historically been less than 10%, that is, less than 10% of the thermal power ("heat") is converted into usable electrical power (Bennett, 1989).

Fig. 5 Diagram of a thermoelectric element. Courtesy of U.S. Atomic Energy Commission.

Fig. 6 Cutaway of the General-Purpose Heat Source Radioisotope Thermoelectric Generator (GPHS-RTG). The GPHS-RTG is capable of producing 300 We at beginning of life. The GPHS-RTG has an overall diameter of 0.422 m and a length of 1.14 m with a mass of about 55.9 kg. Courtesy of DOE/JPL.

Typical thermoelectric materials used in U.S. RTGs have been lead-telluride and silicon-germanium. The silicon-germanium RTGs have had a power decay (mostly the result of the decay of the plutonium-238 heat source) of about 1.6% per year. The lead-telluride RTGs have had a decay about twice that.

Fig. 6 illustrates how all of these parts come together in the General-Purpose Heat Source Radioisotope Thermoelectric Generator (GPHS-RTG) which powered the Galileo orbiter of Jupiter, the Ulysses solar polar orbiter, the Cassini orbiter of Saturn and now the New Horizons spacecraft that has traveled to Pluto and beyond.

Table 2 lists the space nuclear power sources that have been flown by the U.S. With one exception (SNAP-10A) they have all been radioisotope power sources. The former Soviet Union has flown at least 35 space reactors and at least 4 radioisotope power sources. European researchers have written about radioisotope power sources fueled with americium-241 and space reactors.

- Viking Mars Landers 1 and 2 (1975) SNAP-19 (2/Lander @ ~42 We each)
- Voyager 1 and Voyager 2 (1977) MHW-RTG (3/spacecraft @ ~158 We each)
- Galileo (1989) GPHS-RTG (2 @ ~288 We each) (>3-year delay)
- Ulysses (1990) GPHS-RTG (289 We) (>4-year delay)
- Cassini (1997) GPHS-RTG (3 @ ~295 We each)
- New Horizons (2006) GPHS-RTG (1 @ 245.7 We) (most of fuel >21 years old)
- Curiosity Mars Science Laboratory (2011) MMRTG (1 @ ~110 We)
- Perseverance Rover (2020) MMRTG (1 @ ~110 We)

^aThe odd-numbered SNAP power sources used radioisotope heating while the even-numbered SNAP power sources used nuclear reactors to produce the heat.

Radioisotope heater units

Another use for radioisotopes on spacecraft is the production of heat to keep sensitive instruments warm without introducing the potential for electrical interference from an electric heater. Such sources of heat are termed radioisotope heater units (RHUs). An advantage of an RHU is that it doesn't take critical power away from the spacecraft power source to produce the heat.

Fig. 7 shows the parts of a one-watt thermal RHU termed the "Light-Weight Radioisotope Heater Unit (LWRHU)" which has been flown on such missions as the Galileo mission to orbit Jupiter, the Cassini mission to orbit Saturn and on various Mars rovers. The LWRHU produces 1 watt of thermal power ("heat").

Benefits of radioisotope power

Radioisotope power sources are attractive for use inspace under a number of conditions:

Lifetime. Radioisotope power sources are a principal alternative for spacecraft which must operate for a long period of time. (As noted earlier, the two Voyager spacecraft have successfully operated for over 43 years).

Environment. Radioisotope power sources are less vulnerable to external radiation (e.g., Van Allen radiation belts) and to other potentially hostile environments (e.g., meteoroids, Martian dust storms, extreme temperatures (such as experienced on the lunar surface during the lunar day)). (When Pioneer 10 flew past Jupiter it was exposed to a radiation dose on the order of 10^5 rads from electrons and 10^6 rads from protons. The RTGs operated perfectly throughout the jovian encounter).

Self-Sufficiency. Radioisotope power sources make the spacecraft more independent. In this regard, radioisotope power sources have an advantage in being able to operate on the launch pad for full-up systems checkouts prior to launch.

Operational. Radioisotope thermoelectric generators have achieved extremely high reliability. They provide a compact, good power-to-mass (specific power) source of electrical power. The comparatively small exposed area of radioisotope power sources minimizes the radar cross section, attitude control, and structural considerations. Radioisotope heater units can be used to supply heat directly to sensitive spacecraft components without electromagnetic interference.

Fig. 7 Light-weight radioisotope heater unit (LWRHU). Courtesy of DOE/NASA.

Challenges of radioisotope power

In the U.S., the principal challenge facing users of radioisotope power sources is obtaining sufficient quantities of the radioisotope plutonium-238 to provide the necessary thermal power ("heat"). In the late 1980s, the U.S. ceased its main production of plutonium-238 which has caused the U.S. Department of Energy (DOE) to develop alternative sources of plutonium-238.

Related to availability is the issue of cost. In the early days of the radioisotope power program, the users (e.g., NASA or the U.S. Department of Defense) were charged appropriately considering the charter of the U.S. Atomic Energy Commission (predecessor to DOE) to encourage research and use of nuclear power.

The limited supply of plutonium-238 coupled with the cost has caused renewed attention on developing more efficient conversion systems such as "dynamic" conversion (Stirling linear alternators and Brayton and Rankine turbine-alternators). Dynamic conversion systems offer the potential of efficiencies in the range of 20–30% (instead of the 5–10% of static systems) which means a great reduction in the amount of plutonium-238 that must be used.

Some researchers have investigated alternatives to plutonium-238 (such as americium-241 and polonium-210) but these radioisotopes also require a nuclear production infrastructure.

Introduction

Electrical power is essential for the operation of a spacecraft. When that spacecraft must travel far from the Sun or operate for longer periods in hostile environments (such as the long lunar night or the dust storms of Mars) then nuclear power becomes enabling. In response to the need for long-lived, Sun-independent power, the US Atomic Energy Commission (AEC) initiated studies in the 1950s of both space nuclear reactors and space radioisotope power sources. These early concepts were designated by a SNAP number where SNAP stands for Systems for Nuclear Auxiliary Power. Even-numbered SNAP power sources were reactors and odd-numbered SNAP power sources were radioisotope power sources.

K. C. Jordan and J. H. Birden, two researchers working at what was then the AEC's Mound Laboratory, built the first radioisotope thermoelectric generator in 1954 by coupling the thermal power of a radioisotope to thermoelectric elements ("thermocouples"). What Jordan and Birden achieved in 1954 defines the two basic elements of an RTG: a radioisotope heat source and a thermoelectric converter. Fig. 1 shows these two basic elements and their ancillary parts for the current RTG known as the Multi-Mission RTG (MMRTG).

All of the US RTGs flown in space have used the radioisotope plutonium-238 to provide the heat. With a half-life of 87.7 years, plutonium-238 is an excellent choice to power long-lived spacecraft. The chemical and metallurgical form of the plutonium-238 has evolved over the years. For current uses, the plutonium-238 is in the form of a high-temperature ceramic oxide. (The production of plutonium-238 is discussed in Bennett, 2021.)

An RTG basically consists of two components: the heat source (which contains the plutonium-238 and associated containment structures) and the converter. The converter in an RTG consists of an arrangement of thermoelectric couples or elements composed of two legs: a positive-type leg ("p-leg") and a negative-type leg ("n-leg"). In many of the RTGs, the same material was used for both the p-leg and the n-leg, the difference coming from the use of different dopants to produce the p-legs and the n-legs. Like the heat source, the chemical and metallurgical form of the thermoelectric elements has evolved over the years from telluride-based elements in the early SNAPs to an alloy of silicon-germanium. The efficiency with which the thermal power ("heat") is converted into electrical power has varied from around 5% to almost 7%. With the advent of the MMRTG for Mars surface missions, the design reverted to telluride-based thermoelectric elements. Research continues to develop higher efficiency thermoelectric elements as well as dynamic conversion systems such as Brayton, Rankine and Stirling.

Table 1 lists the RTGs flown by the United States. In addition to the 42 US RTGs flown, the United States also flew the first space nuclear reactor (SNAP-10A) in 1965. The former Soviet Union reportedly has flown RTGs on two Earth-orbiting spacecraft (Cosmos 84 and Cosmos 90) and on two lunar rovers (Lunokhod-1 and Lunokhod-2), mostly using polonium-210 as the radioisotope. For the aborted Mars 96 mission, the lander stations carried RTGs and RHUs fueled with plutonium-238. The major effort by the former Soviet Union was reportedly on space nuclear reactors with about 31 (and perhaps 33) BUK thermoelectric reactors used for marine radar observations. Two experimental thermionic reactors (designated "TOPAZ" not to be confused with the misnamed "TOPAZ-II" Russian reactor tested in the United States) were flown on Earth-orbiting satellites Cosmos 1818 and Cosmos 1867. European researchers have studied the use of RTGs, notably powered by americium-241. Chinese researchers have developed RTGs fueled with plutonium-238 as demonstrated with their Chang'e 4 lunar mission.

Fig. 1 Multi-Mission Radioisotope Thermoelectric Generator (MMRTG). The two basic elements of an RTG are the radioisotope heat source and the thermoelectric converter. The heat source is illustrated in red and labeled "8 GPHS module stack" where "GPHS" stands for General-Purpose Heat Source. Source: DOE/NASA.

• SNAP-27 (> 70 We each)
Lincoln Experimental Satellites (Communications)
• LES-8 and LES-9 (1976) MHW-RTG (2/spacecraft @ ~ 154 We each)
Interplanetary Missions
• Pioneer 10 (1972) and Pioneer 11 (1973) SNAP-19 (4/spacecraft @ ~ 40 We each)
• Viking Mars Landers 1 and 2 (1975) SNAP-19 (2/Lander @ ~ 42 We each)
• Voyager 1 and Voyager 2 (1977) MHW-RTG (3/spacecraft @ ~ 158 We each)
• Galileo (1989) GPHS-RTG (2 @ ~ 288 We each) (> 3 -year delay in launch)
• Ulysses (1990) GPHS-RTG (289 We) (> 4 -year delay in launch)
• Cassini (1997) GPHS-RTG (3 @ ~ 295 We each)
• New Horizons (2006) GPHS-RTG (245.7 We) (most of fuel had > 21 years decay)
• Curiosity Mars Science Laboratory (2011) MMRTG (~ 115 We) (> 2 -year delay)

Transit Navy navigational satellites

Researchers at the Johns Hopkins University Applied Physics Laboratory (JHU/APL) developed the technique of using the Doppler shifting of telemetry signals from orbiting spacecraft for navigation. Beginning with the Transit-4A and Transit-4B satellites in 1961, JHU/APL included RTGs on board six navy navigational satellites to provide auxiliary power to supplement the solar power. The prime contractor for all but one of these RTGs was The Martin Company (Nuclear Division), which is now part of Teledyne Energy Systems. The US Atomic Energy Commission (now part of DOE) provided these RTGs to JHU/APL for the US Navy. (Of the six RTG-powered Transit satellites, one, Transit-5BN-3, failed to achieve orbit on April 21, 1964.)

Fig. 2 is a photograph of a technician holding a SNAP-3B RTG of the type used on the Transit-4A and Transit-4B navigational satellites.

Fig. 3 is a cutaway of the SNAP-3B RTG system which also illustrates how an RTG works. The SNAP-3B RTG provided about 2.7 We of electrical power from 52.5 Wt of thermal power in an envelope 12.1-cm in diameter by 14-cm high and a mass of 2.1 kg. The thermal-to-electric conversion was achieved by 27 spring-loaded, series-connected pairs of lead telluride thermoelectric elements with an efficiency slightly over 5%.

1. The radioisotope fuel decays spontaneously emitting alpha particles that produce heat upon absorption
2. Thermoelectric elements (thermocouples) convert heat directly to electrical power
3. Electrical power is tapped from terminals connected to the thermoelectric elements (the outer shell acts as a radiator to remove waste heat).

Fig. 4 illustrates how the SNAP-3B RTG was installed on a Transit-4 navigational satellite. Overall, both SNAP-3B RTGs were extremely successful and more than met their five-year lifetime requirement.

Fig. 2 SNAP-3B RTG. Source: US Atomic Energy Commission.

Fig. 3 Cutaway view of a generic radioisotope thermoelectric generator (RTG) (based on the SNAP-3B design) and diagram of how an RTG functions. Source: US Atomic Energy Commission.

Fig. 4 Paul J. Dick installing a SNAP-3B RTG on a Transit Navy navigational satellite (1961). Source: US Atomic Energy Commission.

For the follow-on Transit 5-BN series of navigational satellites, a higher-powered RTG was needed. A new RTG designated SNAP-9A was designed and fabricated to produce 25 We at a nominal 6 V for 5 years in space after 1 year of storage on Earth.

Fig. 5 is a photograph of a SNAP-9A RTG which had 70 pairs of series-connected lead-telluride-based thermoelectric couples assembled in 35 modules of two couples each. The couples were spring-pressed against the heat source block which produced about 525 Wt. Some of the waste heat from the SNAP-9A RTGs was used to maintain electronic instruments within the Transit 5 BN satellites at a temperature near 293 K and the rest of the heat was radiated into space.

The Transit 5BN-1 and Transit 5 BN-2 satellites were the first totally nuclear powered satellites. They gave the US Navy a power source resistant to radiation that enabled US Navy ships to navigate anywhere in the world.

For the JHU/APL TRIAD satellite, a different RTG, designated the TRANSIT RTG, was employed. **Fig. 6** is a cutaway of the TRANSIT RTG showing the heat source which radiated to the lead-telluride-based thermoelectric couples. The TRANSIT RTG was designed to produce 30 We after 5 years. While an electronic failure on the TRIAD satellite precluded obtaining RTG power data, the continued operation of the satellite over the decade or more after the 1972 launch showed that the TRANSIT RTG was providing the required power.

Nimbus-3 meteorological satellite

Under the overall management of NASA's Goddard Space Flight Center (GSFC), the Nimbus-3 meteorological satellite, which was launched on April 14, 1969, was NASA's first use of nuclear power on a spacecraft. (An earlier launch designated Nimbus-B1 on May 18, 1968 had to be aborted and the RTGs recovered.) For the Nimbus-3 mission, the AEC provided an evolved power source termed SNAP-19 which grew out of the SNAP-9A development program. **Fig. 7** is a photograph of the two Nimbus-3 SNAP-19 RTGs.

The two SNAP-19 RTGs enabled the Nimbus-3 satellite to operate in a full-time duty cycle. This opened the way for NASA to use RTGs in future missions.

Early Apollo Lunar Surface Experiments Package (EASEP)

For the Apollo 11 mission (the first human landing on the Moon) the astronauts assembled a lunar experiments package powered by solar cells and kept warm with two 15-Wt radioisotope heater units (RHUs). An RHU is basically a container of a radioisotope

Fig. 5 Photograph of a SNAP-9A RTG of the type used on the Transit-5BN satellites. The SNAP-9A RTG was designed to produce 25 We in an envelope of 26.7-cm high by 50.8-cm across the fins and a mass of about 12.3 kg. Source: US Atomic Energy Commission.

Fig. 6 Cutaway of the TRANSIT RTG. The TRANSIT RTG was designed to provide 30 We after 5 years. The mass of the TRANSIT RTG was about 13.6 kg and the distance across the flats was about 61 cm. Source: TRW under contract to the AEC.

Fig. 7 Photograph of models of the two Nimbus-3 SNAP-19 RTGs shown in the mounted configuration for the Nimbus-3 satellite. The two RTGs produced 56.4 We at launch. The RTGs were 26.7 cm high and 53.8 cm across the heat-radiating fins. The overall mass was 16.3 kg. Source: US Department of Energy.

(plutonium-238 in the United States) that provides heat from the natural decay of the radioisotope. Fig. 8 is a diagram of the most recent US RHU, known as the Light-Weight Radioisotope Heater Unit (LWRHU) which has been used on the Galileo, Cassini and various Mars missions (see Table 2). Table 2 lists the NASA missions enabled by radioisotope heater units.

Apollo Lunar Surface Experiments Packages (ALSEP)

The long (14-Earth-day) lunar nights and lunar dust led to the use of RTGs to power the Apollo Lunar Surface Experiments Packages (ALSEPs) installed on the Moon by the crews of Apollo 12, 14, 15, 16, and 17. Fig. 8 is a cutaway of the SNAP-27 RTG. The design took advantage of the presence of astronauts who would insert the heat source into the converter on the Moon (Fig. 9). (As noted earlier, two radioisotope heater units were used on the Apollo 11 Early Apollo Experiments Package, EASEP.)

On November 19, 1969, Apollo 12 astronauts Charles Conrad, Jr. and Alan L. Bean assembled the first nuclear-powered ALSEP. With the success of the Apollo 12 SNAP-27 RTG, four more SNAP-27-RTG-powered ALSEPs (Apollo missions 14-17) were installed on the Moon. Fig. 10 shows astronaut Alan Bean removing the heat source from its container prior to insertion into the converter (shown in the foreground). (A sixth SNAP-27 RTG safely reentered the Earth's atmosphere after the abort of the Apollo 13 mission.)

All five SNAP-27 RTGs more than met their prelaunch requirements thereby enabling the ALSEPs to gather long-term scientific data on the internal structure and composition of the Moon.

Lincoln experimental satellites 8 and 9

The next RTG developed more than doubled the power of the SNAP-27 RTGs and more than quadrupled the power of the SNAP-19 RTGs. Developed by General Electric (now part of Lockheed-Martin) and termed the “Multi-Hundred Watt Radioisotope Thermoelectric Generator (MHW-RTG),” these RTGs powered the MIT Lincoln Laboratory (MIT/LL) satellites designated LES-8 and LES-9 (LES stands for Lincoln Experimental Satellite). The LES-8/9 satellites, which were launched together on 14 March 1976, were to test advanced technologies for strategic communications. Each LES carried two MHW-RTGs, producing about 154 We at 26.5 V each at beginning of mission by means of 312 thermoelectric couples using a new alloy based on silicon-germanium. Fig. 11 is a cutaway of the MHW-RTG.

The successful use of MHW-RTGs on the two US Air Force satellites LES-8/9 helped pave the way for their use on NASA’s Voyager 1 and Voyager 2 spacecraft (which were built and managed by JPL). For LES-8/9, the MHW-RTGs more than met their five-year life-time requirement providing reliable, continuous power even during the daily 70-min eclipses of the Sun by Earth. Fig. 12 illustrates the LES-8/9 concept.

Interplanetary missions

Radioisotope power was enabling for the next set of NASA missions—flights to the outer planets. Simply put, in the cold, dark regions of the outer Solar System or the cold, dusty deserts of Mars, there was no other long-term option. Some of the greatest robotic explorers of all time were powered by RTGs: Pioneer, Viking, Voyager, Galileo, Ulysses, Cassini, New Horizons and Curiosity Mars Science Laboratory.

Fig. 11 Cutaway of the Multi-Hundred Watt Radioisotope Thermoelectric Generator (MHW-RTG). The MHW-RTG produced about 154 We per RTG at beginning of mission by means of 312 silicon-germanium alloy thermoelectric couples. The mass for the LES-8/9 MHW-RTGs was 39.69 kg within an envelope 58.31-cm long by 39.73-cm in diameter. Source: US Department of Energy.

Fig. 12 Lincoln Experimental Satellites 8 and 9 providing reliable communications among mobile military platforms. The two MHW-RTGs on each spacecraft are mounted on the ends of the spacecraft. Source: MIT Lincoln Laboratory.

Pioneer 10 and Pioneer 11

For the Pioneer 10 and Pioneer 11 missions to Jupiter (which were managed by NASA's Ames Research Center), the SNAP-19 RTG was improved by Teledyne raising the beginning of mission power from 28.2 We per RTG on Nimbus to 40.3 We per RTG. The power conversion efficiency was also raised from 4.5% for the Nimbus-3 SNAP-19 RTGs to 6.2% for the Pioneer SNAP-19 RTGs. Related to this, the specific power was raised from 2.1 We/kg (Nimbus RTGs) to 3.0 We/kg (Pioneer RTGs). **Fig. 13** shows a cutaway of the Pioneer SNAP-19 RTG.

Both Pioneer 10 (launched on March 2, 1972) and Pioneer 11 (launched on April 5, 1973) successfully navigated the asteroid belt and became the first spacecraft to fly by Jupiter. Pioneer 10 paved the way for exploration of the outer Solar System—"for Voyager to tour the outer planets, for Ulysses to break out of the ecliptic, for Galileo to investigate Jupiter and its satellites, and for Cassini to go to Saturn and probe Titan" (NASA Fact Sheet on "The Pioneer Missions"). Thanks to the excellent performance of the two spacecraft and their RTGs power sources, NASA directed Pioneer 11 to fly by Saturn, making it the first spacecraft to encounter the ringed world. Pioneer 10's radiation measurements at Jupiter were crucial in designing the Voyager and Galileo spacecraft. Both spacecraft continued to operate decades after launch, becoming humanity's first interstellar messengers (see illustration in **Fig. 14**).

Viking Lander 1 and Viking Lander 2

To meet the requirements of being encapsulated for the voyage to Mars and to operate on the surface of Mars, the basic SNAP-19 RTG design was modified to include a dome reservoir of gas. Each Viking Lander carried two SNAP-19 RTGs which were to produce a minimum of 35 We during the "primary mission" (90 days on the surface of Mars). The Viking SNAP-19 RTGs more than met their 90-day requirement and operated for years after their 1976 landings thereby providing valuable scientific data on the surface of Mars. (It was estimated that the SNAP-19 RTGs on Viking Lander 1 were capable of providing sufficient power for operation until 1994—18 years beyond the mission requirement.) Using a model, **Fig. 15** shows the location of the two Viking SNAP-19 RTGs on a Viking Lander. (Overall management of the Viking Lander program resided at NASA's Langley Research Center.)

Voyager 1 and Voyager 2

The Multi-Hundred Watt RTG design originally flown in 1976 on the LES-8/9 satellites was modified for the Voyager 1 and Voyager 2 missions principally by reinforcing the converter case and removing an iridium canister. The net effect was to reduce the mass of

Fig. 13 Cutaway of the Pioneer SNAP-19 RTG. Beginning of mission power was 40.3 We per RTG. The height was 28.2 cm and the fin span was 50.8 cm. The average mass was 13.6 kg per RTG. Source: US Department of Energy.

Fig. 14 Artist's conception of Pioneer spacecraft entering interstellar space. Each Pioneer spacecraft carried four SNAP-19 RTGs, two each mounted on booms. The high-gain antenna is 2.7 m in diameter and the spacecraft mass is 270 kg. Source: NASA.

Fig. 15 Location of the Viking SNAP-19 RTGs on the Viking Lander. Each Viking SNAP-19 RTG produced an average beginning of mission power of 42.7 We. The mass of the Viking SNAP-19 RTG was 15.2 kg. The height of the Viking SNAP-19 RTG (with dome) was 40.4 cm and the diameter across the fins was 58.7 cm. Source: US Department of Energy and NASA.

the Voyager MHW-RTGs by about 2 kg. Whereas each Lincoln Experimental Satellite carried two MHW-RTGs, each Voyager spacecraft carried three MHW-RTGs, each producing an average of 158 We at about 30 V at beginning of mission.

The original objective of the Voyager 1 and Voyager 2 missions was to fly past Jupiter and Saturn. The successful accomplishment of this objective and the outstanding power performance of the MHW-RTGs allowed NASA to send Voyager 2 on to Uranus and Neptune. Both Voyagers are still operating now in interstellar space over 42 years after their 1977 launches (see Fig. 16).

Fig. 16 Artist's conception of Voyager 1 in interstellar space. The three MHW-RTGs are shown on the boom below the spacecraft. The Voyager antenna is 3.7 m in diameter and the spacecraft mass is 825 kg. Source: NASA/JPL.

Galileo

For NASA's Galileo Jupiter orbiter spacecraft and for the European Space Agency's Ulysses solar polar orbiter, a new, more powerful RTG was designed and produced: the General-Purpose Heat Source Radioisotope Thermoelectric Generator (GPHS-RTG). Versions of the GPHS-RTG would go on to be used on the Cassini Saturn orbiter and the New Horizons mission to Pluto and beyond. With new plutonium-238 fuel at the time of fueling, the GPHS-RTG was capable of providing at least 300 We making the GPHS-RTG the most powerful RTG ever flown.

As illustrated in Fig. 17, the GPHS-RTG is composed to two main elements: the general-purpose heat source (GPHS) assembly and the converter. The GPHS assembly consists of 18 modules, each containing four encapsulated fuel pellets ("fueled clads") that combined (using new plutonium-238 fuel) produced about 245 Wt per module for a total of about 4410 Wt which the converter with its 572 silicon-germanium alloy thermoelectric elements converted into at least 285 We at beginning-of-mission (BOM). (At the time of fueling, the GPHS-RTG was capable of producing over 300 We.)

Fig. 18 is an artist's illustration of the Galileo spacecraft in orbit about Jupiter. The Galileo mission consisted of an Orbiter (powered by two GPHS-RTGs) and a Probe which entered the Jovian atmosphere. In addition to the GPHS-RTGs on the Galileo Orbiter, both the Orbiter and the Probe carried radioisotope heater units for thermal management. The Galileo spacecraft was launched on October 18, 1989 and, after various planetary flybys transiting some 3.7 billion kilometers, reached Jupiter on December 7, 1995. The Galileo spacecraft was the first RTG-powered spacecraft to be launched on Space Shuttle.

Galileo was the first spacecraft to orbit an outer planet; it orbited Jupiter for almost 8 years, making close passes by all its major moons. Measurements made by Galileo allowed scientists to determine that Jupiter's icy moon Europa probably has a subsurface ocean with more water than the total amount found on Earth. Magnetic data indicated that the moons Ganymede and Callisto may also have a liquid saltwater layer. The indications of water on Europa, Ganymede and Callisto are of keen scientific interest because water is thought to be one of the precursors to the origin of life. As a result of the Galileo mission, NASA is developing a mission to study Europa in more detail even as NASA's Juno mission is providing close-up data on Jupiter.

At beginning of mission the two Galileo GPHS-RTGs produce a combined 577 We. The power was about 2% less than it could have been because there had been a three-year delay following the Space Shuttle Challenger accident.

On September 21, 2003, after 14 years in space and 8 years orbiting Jupiter and running out of propellant for spacecraft control, Galileo was sent into the atmosphere of Jupiter so that it would not accidentally contaminate satellites such as Europa.

Ulysses

Launched on October 6, 1990 from Space Shuttle Discovery, the Ulysses spacecraft (shown in an artist's conception in Fig. 19) was a joint European Space Agency (ESA)-NASA-designed five-year mission to study the never-before-examined north and south poles

Fig. 17 General-Purpose Heat Source Radioisotope Thermoelectric Generator. The GPHS-RTG was capable of producing at least 300 We at time of fueling. The GPHS-RTG overall diameter was 0.422 m with a length of 1.14 m and a mass of about 55.9 kg (Galileo/Ulysses). Source: GE (under DOE contract) and DOE/NASA.

Fig. 18 Artist's concept of the Galileo Orbiter at Jupiter receiving signals from the Galileo Probe which has entered the Jovian atmosphere. Galileo carried two GPHS-RTGs mounted on booms. The magnetometer boom extends 11 m to one side; the mass of the Orbiter was 2223 kg. Source: NASA/JPL.

Fig. 19 Artist's illustration of Ulysses and the Sun. Ulysses was powered by a GPHS-RTG (shown mounted on the lower side). The Ulysses spacecraft carried nine scientific instruments and had a mass of 371 kg. Source: ESA/NASA/JPL.

of the Sun. To do that, Ulysses made an unprecedented gravity assist maneuver at Jupiter to hurl itself out of the ecliptic plane and into its solar polar orbit. Since sunlight at Jupiter is about 25 times less intense than at Earth, Ulysses carried a GPHS-RTG for power. The beginning of mission power was 289 We (it would have been higher but there was a four-year launch delay following the 1986 Space Shuttle Challenger accident). Thanks to the long-lived GPHS-RTG, Ulysses was able to operate 13 years longer than the 5-year goal.

Cassini

The Cassini Saturn orbiter with ESA's Huygens probe was launched on October 15, 1997. The Cassini spacecraft was powered by three GPHS-RTGs. Additionally, as with Galileo, Light-Weight Radioisotope Heater Units (LWRHUs) provided thermal power to Cassini and to the Huygens probe that was to land on Titan, Saturn's largest satellite (Fig. 20).

Launched by a Titan/Centaur rocket, Cassini arrived at Saturn on July 1, 2004 after two gravitational assists at Venus, one at Earth and one at Jupiter. The Huygens Probe was released on December 24, 2004 and descended to Titan on January 14, 2005.

The three GPHS-RTGs produced a total of 885 We at beginning of mission and 633 We at end of mission.

Cassini provided a wealth of data on Saturn and its satellites finding evidence that Saturn's moon Enceladus very likely has an ocean under its surface ice and, with Huygens, that Saturn's largest moon, Titan, has intriguing pre-biotic chemistry.

After two extensions of the original 4-year mission, Cassini was sent into the atmosphere of Saturn on September 15, 2017 to avoid accidentally contaminating the satellites (of particular concern was Enceladus which, like Europa, may have a large subsurface water ocean).

New Horizons

THE 478-kg New Horizons spacecraft, built by the Johns Hopkins University's Applied Physics Laboratory, was launched on January 19, 2006 to begin a 9.5-year voyage to Pluto and its satellites. New Horizons is powered by a single GPHS-RTG which produced about 245.7 We at beginning of mission (more power would have been possible had DOE not been forced to use some "old" fuel).

New Horizons successfully flew past Pluto on July 14, 2015 sending back very valuable scientific information on what was once termed the ninth planet. New Horizons has gone on to fly past the Kuiper Belt object (KBO) Arrokoth and is now making ground-breaking measurements in the Kuiper Belt. Fig. 21 is an illustration of New Horizons.

Curiosity Mars Science Laboratory

For NASA's Curiosity Mars Science Laboratory rover, a new RTG, termed the Multi-Mission Radioisotope Thermoelectric Generator (MMRTG), was developed. The MMRTG is designed to operate on planetary surfaces or in deep space. Like the GPHS-RTG, the

Fig. 20 Artist's illustration of the Cassini spacecraft just after release of the European Space Agency (ESA) Huygens Probe to land on Titan. Two of the three GPHS-RTGs can be seen in the upper left of the figure. Cassini was 6.7 m high by 4 m wide with a mass at launch of 5712 kg (including propellant, Huygens Probe, adapter, etc.) Source: NASA/JPL.

Fig. 21 Artist's conception of the New Horizons spacecraft at Pluto. Pluto's largest satellite, Charon, is in the background. The New Horizons GPHS-RTG is shown on the left side of the spacecraft. New Horizon has a triangular-shaped body almost 0.76 m thick. Source: JHUAPL/SwRI.

MMRTG uses the modular General-Purpose Heat Source but its thermoelectric technology harkens back to the Pioneer and Viking SNAP-19 RTGs. The MMRTG is designed to produce at least 110 We at beginning of mission.

Fig. 22 illustrates the components of the MMRTG and shows the location on the Curiosity rover.

Curiosity was launched on November 26, 2011 and landed in the Gale crater on Mars on August 6, 2012. Since then Curiosity has moved across Gale crater and is climbing Aeolis Mons (Mount Sharp). Curiosity has made a number of exciting discoveries including evidence that Gale crater was likely the floor of an ancient stream or pond (**Fig. 23**).

Fig. 22 Cutaway of the Multi-Mission Radioisotope Thermoelectric Generator (MMRTG). The MMRTG produces power from the heat emanating from the eight GPHS modules shown in red. Source: DOE.

Conclusions

Radioisotope power sources, both RTGs and RHUs, have been enhancing and/or enabling challenging space missions for over 58 years. Since 1961, the United States has successfully launched 42 RTGs on 24 space missions along with hundreds of RHUs. The RTGs have powered the Apollo Lunar Surface Experiments Packages; the Pioneer flybys of Jupiter and Saturn; the Viking Mars Landers; the Voyager flybys of Jupiter, Saturn, Uranus, and Neptune; the Galileo orbital exploration of Jupiter; the Ulysses solar polar explorer; the Cassini orbital exploration of Saturn; the New Horizons mission to Pluto and the Kuiper Belt and the Curiosity Mars Science Laboratory.

Introduction

Radioisotope power sources/systems (RPSs) have been enabling for some of the most challenging space missions such as the Pioneer 10/11 flights to Jupiter, Saturn and beyond; the Viking Mars Landers 1/2; the Voyager 1/2 flights to Jupiter, Saturn, Uranus, Neptune and beyond; the Galileo Jovian orbiter, the Ulysses solar polar orbiter; the Cassini Saturn orbiter; the New Horizons flight to Pluto and beyond; and the Curiosity and Perseverance Marsrovers. All of these missions have been powered by radioisotope thermoelectric generators (RTGs), that is, radioisotope power sources that produce electrical power by means of the thermoelectric effect. A number of these missions also employed radioisotope heater units (RHUs) to provide thermal power ("heat") to sensitive components on the spacecraft. **Fig. 1** provides a visual summary of these U.S. RPS missions. **Table 1** summarizes the RTGs flown by the U.S. (Bennett et al., 1984, 2006).

The former Soviet Union reportedly has flown RTGs on two Earth-orbiting spacecraft (Cosmos 84 and Cosmos 90) and on two lunar rovers (Lunokhod-1 and Lunokhod-2), mostly using polonium-210 as the radioisotope. For the aborted Mars 96 mission, the

*NASA retired.

Table 1 Uses of Radioisotope Thermoelectric Generators (RTGs) by the United States (Spacecraft/Year Launched/Type of RTG/Beginning-of-Mission Power) (Bennett et al., 1984, 2006).

Transit Navy Navigational Satellites

- Transits 4A and 4B (1961) SNAP-3B (2.7 We)
- Transits 5BN-1 and 5BN-2 (1963) SNAP-9A (≥ 25 We)
- Transit TRIAD (1972) Transit-RTG (35 We)

Nimbus-3 Meteorological Satellite

- SNAP-19B RTGs (1969) (2 @ 28 We each)

Apollo Lunar Surface Experiments Packages

- Apollos 12 (1969), 14 (1971), 15 (1971), 16 (1972), 17 (1972)
- SNAP-27 (> 70 We each)

Lincoln Experimental Satellites (Communications)

- LES-8 and LES-9 (1976) MHW-RTG (2/spacecraft @ ~ 154 We each)

Interplanetary Missions

- Pioneer 10 (1972) and Pioneer 11 (1973) SNAP-19 (4/spacecraft @ ~ 40 We each)
- Viking Mars Landers 1 and 2 (1975) SNAP-19 (2/Lander @ ~ 42 We each)
- Voyager 1 and Voyager 2 (1977) MHW-RTG (3/spacecraft @ ~ 158 We each)
- Galileo (1989) GPHS-RTG (2 @ ~ 288 We each) (> 3 -year delay in launch)
- Ulysses (1990) GPHS-RTG (289 We) (> 4 -year delay in launch)
- Cassini (1997) GPHS-RTG (3 @ ~ 295 We each)
- New Horizons (2006) GPHS-RTG (245.7 We) (most of fuel had > 21 years decay)
- Curiosity Mars Science Laboratory (2011) MMRTG (~ 115 We) (> 2 -year delay)
- Perseverance rover (2020) MMRTG (~ 110 We)

lander stations carried RTGs and RHUs fueled with plutonium-238. European researchers have studied the use of RTGs, notably powered by americium-241. Chinese researchers have developed RTGs fueled with plutonium-238 as demonstrated with their Chang'e 4 lunar mission.

Looking to the future, there are technology options available or that could be developed to increase the efficiency of converting thermal power to electrical power. A higher efficiency RPS would allow obtaining the desired electrical power with less plutonium-238, a radioisotope that is in limited supply (although more is being produced). Similarly, a higher efficiency RPS could provide the desired amount of power in a smaller package. Thus, from the beginning of the RPS program, there have been studies and experiments to develop and qualify higher efficiency conversion systems such as improved thermoelectric materials and dynamic conversion systems. Some of the principal conversion systems will be discussed in the next sections.

Mission requirements

For future RTGs, in 2016, NASA's RPS Program conducted a study to determine possible options for a next-generation of RTGs that could be produced in the late 2020s and would be useful throughout the following 20 years. The objective of the study was "... to determine the characteristics of the next RTG that would "best" fulfill NASA's Planetary Science Division (PSD) mission needs." This study was limited to systems that convert heat to electricity using thermoelectric couples. "Best" was defined as a confluence of the following factors (Woerner 2017):

- An RTG that would be useful across the Solar System
- An RTG that maximizes the types of missions: flyby, orbiter, lander, rover, boats, submersibles, balloons
- An RTG that has reasonable development risks and timeline
- An RTG value (importance, worth and usefulness) returned to PSD for investment, as compared with retaining existing baseline systems

A thermoelectric converter is what is termed a "heat engine" because it depends on heat flow and temperature differences for its operation. To increase efficiency (amount of thermal power converted to electrical power): raise the temperature on the "hot side" (end of the thermoelectric element closest to the radioisotope heat source) and/or lower the temperature on the "cold side" (the end of the thermoelectric element that conducts the unused or "waste" heat outside the RTG). The temperature difference can be likened to the pressure difference that pushes fluids through pipes. Similarly, as will be seen in the sections on dynamic conversion systems, temperature difference is also a critical feature in achieving higher efficiency.

In assessing thermoelectric materials there are three critical properties: the Seebeck coefficient, the electrical resistivity, and the thermal conductivity. The Seebeck coefficient is the voltage produced by each degree of temperature difference; it is a property of the material used. An "ideal" thermoelectric material would have a high Seebeck coefficient, low electrical resistivity (so that very little of the generated electric current is turned into heat), and low thermal conductivity (so that the temperature difference across the thermoelectric elements is increased to provide the "push" for the electrical current).

Currently, since 1976, as shown in Fig. 2, the U.S. has three extant flight RTGs that have been used in space missions.

The Multi-Hundred Watt RTG (MHW-RTG) was designed for two missions: the U.S. Air Force (USAF) Lincoln Experimental Satellites 8 and 9 (LES-8/9) and NASA's two Voyager interplanetary/interstellar spacecraft (Voyagers 1 and 2). (The MHW-RTG was also considered for the Galileo Jovian orbiter.) The MHW-RTG is capable of producing ~158 We at beginning of mission (BOM) with a mass of less than 38 kg. The General-Purpose Heat Source RTG (GPHS-RTG) is capable of producing 300 We at BOM with a mass of less than 56 kg. By virtue of the design requirements (outer-planet missions), the MHW-RTG and the GPHS-RTG operate in a vacuum (although a cover gas could be applied if needed). The Multi-Mission RTG (MMRTG) is a sealed system that is designed to operate in space or in planetary atmospheres. The MMRTG can produce >110 We at BOM with a mass of ~45 kg.

As illustrated in Fig. 3, from the RPS mission studies three classes of missions were identified for RPS mission concepts. End-of-mission (EOM) powers ranged from <150 to >600 We (Woerner, 2017).

Improved thermoelectric materials

Both for space applications and Earth-based commercial applications, there has been a focus on improving the efficiency of thermoelectric materials. This research generally takes the form of developing high-temperature materials with a high Seebeck coefficient, a low thermal conductivity and a high electrical conductivity. Unfortunately, materials with a low thermal conductivity also tend to have a low electrical conductivity. Thus, a tradeoff or compromise must be made.

To improve the efficiency of the MMRTG, researchers at NASA's Jet Propulsion Laboratory investigated skutterudites, a cobalt arsenide mineral named after the city of Skotterud, Norway. Skutterudites offer the potential for lowering the thermal conductivity. The inclusion of skutterudites-based thermoelectric elements was projected to increase the efficiency of the "enhanced" MMRTG (eMMRTG), allowing the production of ~145 We versus the 110 We of the MMRTG.

Considering a target operating temperature range of about 1275 K (hot side) and 475 K (cold side), various other materials such as zintl (named for the German chemist Eduard Zintl), lanthanum telluride (La₃-xTe₄) as well as segmented, cantilevered and multicouples have been or are being considered. Segmented thermoelectric elements (elements composed of more than one material)

Fig. 2 Flight Radioisotope Power Sources for Current Missions. (NOTE: The GPHS-RTG is currently powering the New Horizons mission that flew past Pluto. The MHW-RTG is currently powering the two Voyager spacecraft which have left the Solar System. The MMRTG is currently powering the Curiosity Mars Science Laboratory and will power the “Mars 2020 is now named ‘Perseverance’.”)

Fig. 3 The RPS mission studies, sorted by mission class and end-of-mission (EOM) power (Woerner, 2017).

allow the optimization of thermoelectric properties over the temperature range of the thermoelectric element. (Zintl phases are a group of high-melting intermetallic compounds that are poor conductors.)

In addition to developing improved materials design considerations such as having a modular RTG that would allow adaptability to different missions are another avenue of research. Fig. 4 shows conceptually how such a segmented modular RTG might be designed so that in the example shown powers ranging from 50 to 500 W could be produced by “stacking” more RTG modules (Zakrajsek et al., 2017).

In addition to developing new thermoelectric materials and new RTG designs, there are options to improve existing RTG concepts using technologies and processes that have been developed since those RTGs were designed. For example, there are several aspects of the GPHS-RTG that can be improved to provide more power per kilogram (Vining and Bennett, 2010). Also, there are proposals to cascade the thermoelectric elements, that is, in effect, build a second thermoelectric converter “outside” the one closest to the heat source so that some of the waste heat from that first converter can be converted into electrical power by the second converter.

Dynamic conversion systems

Most of the electrical power generated on Earth comes from dynamic machinery such as turbine-alternators which use the heat produced by fossil fuels or nuclear reactions to pump a fluid (e.g., water) to turn an alternator. The process depends upon

Fig. 4 Segmented Modular Radioisotope Thermoelectric Generator Concept. The Segmented Modular RTG would be designed to allow flexibility in power production by using a modular approach to the fabrication of the RTG. Source: NASA.

a fundamental feature of electromagnetism, namely, that a changing magnetic field will produce an electric current, a phenomenon termed Faraday's law of induction (named for Michael Faraday who discovered electromagnetic induction in 1831). In general, dynamic conversion systems are two-to-three (or more) times as efficient as static conversion systems such as thermoelectrics. Thus, dynamic conversion offers the potential to produce the same amount of power as an RTG but with much lower amount of the radioisotope fuel or higher power for the same amount of fuel as the RTG. Moreover, dynamic systems are scalable (on Earth they are in the multi-megawatt range) and they can be operated at lower temperatures than some RTGs, hence, making the use of more conventional materials easier. Three types of dynamic conversion will be considered in the following sections: Brayton, Rankine and Stirling.

Closed Brayton cycle

The Brayton cycle (named after the American engineer George Brayton) is a thermodynamic cycle that can be used to produce power such as in a jet engine or a power plant. In the closed Brayton cycle (CBC), an inert gas working fluid (e.g., a mixture of helium and xenon) is heated and re-circulated through a compressor and turbine coupled to a rotary alternator. **Fig. 5** is a composite diagram showing the features of the closed Brayton cycle and the Rankine cycle (which has some similar features). As a Brayton radioisotope power source, the working fluid (gas) is heated by the radioisotope heat source then expanded through the turbine which cools the gas while rotating the alternator. The gas then is pressurized by the compressor. Waste heat is rejected to space by means of the radiator. The rotating alternator provides alternating-current (AC) power to the spacecraft. Cycle efficiency is improved by using a recuperator to pre-heat the gas before it returns to the heat source. (In the Rankine system that function is carried out by a similar subsystem called the "regenerator".) (Mason and Schreiber, 2007).

NASA began work on the Brayton system in the 1960s, taking the program through kilowatt-class Brayton power conversion systems as well as to lower powers in the hundreds of watts range. NASA selected Brayton converters for its planned 200 kWe

Fig. 5 Generic diagram of a Radioisotope Brayton/Rankine Power conversion system. Source: DOE.

reactor-powered Jupiter Icy Moons Orbiter. DOE also funded development in the 1970s and later in the 1980s, of Brayton technology (Brayton Isotope Power Systems, BIPS) through its Dynamic Isotope Power System (DIPS) program (AiResearch Manufacturing Company of Arizona, 1978). Fig. 6 shows the Mini-Brayton Rotating Unit (Mini-BRU) which was fabricated by AiResearch and which was capable of producing 500–2100 We at an efficiency up to 30% (compared to the less than 10% efficiency of thermoelectric converters). Thousands of hours of successful operation were achieved on the Mini-BRU (Mason and Schreiber, 2007).

Studies in the late 1980s and early 1990s by Rocketdyne led to the design of a 2.5 kWe Brayton power module illustrated in Fig. 7. Efficiencies in the range of 20% were calculated. Versions of this concept could be used to power the first lunar outpost as well as high-power spacecraft (Rocketdyne, 1992).

Fig. 6 Mini-Brayton Rotating Unit (Mini-BRU). The Mini-BRU was capable of producing up to 2100 We with a mass of 17 kg. (NOTE: Other components not shown.) Source: NASA.

Fig. 7 Components of the proposed 2.5 kWe Modular DIPS Power Conversion Unit (PCU). Overall dimensions for the 2.5 kWe module are $2.44 \times 3.55 \times 0.5$ m (Rocketdyne, 1992).

More recently, Creare, Inc., using its micro-turbomachinery technology and working with Rocketdyne has developed a small Brayton unit that fits nicely into the lower power (hundreds of watts or less) regime often filled with RTGs. Fig. 8 shows the conceptual design (Breedlove et al., 2019).

Rankine cycle

Like the Brayton cycle, the Rankine cycle (named for Scottish professor William John Macquorn Rankine) converts heat into mechanical work and/or electrical power. The Rankine cycle accomplishes this by heating the working fluid until there is a phase change (e.g., from liquid to vapor). Many terrestrial power plants operate by heating water until it becomes steam; in essence, a Rankine cycle. The first U.S. RPS operated with the Rankine cycle to produce electrical power (see Fig. 9). Fig. 5 illustrates the overall Rankine cycle in a radioisotope power source.

Fig. 8 Turbo-Brayton Converter concept. Predicted performance: 355 We at an efficiency of 26.3% and a specific power of 21.6 We/kg. Source: Creare (2018) *Turbo-Brayton Converter for Radioisotope Power Systems, RPS Community Review*.

Fig. 9 SNAP-1 turbomachinery package with shaft assembly shown separately. Source: Thompson Ramo Wooldridge, Inc. for U.S. Atomic Energy Commission.

SNAP-1 was designed to produce ~ 500 We of electrical power by using a planned radioisotope heat source to boil liquid mercury at a temperature of ~ 977 K to drive a miniature turbine-alternator which would then be pumped back to the boiler to complete the cycle. The overall efficiency was just under 10% in a mass of 5.9 kg (without the heat source). Given that this was the first Rankine RPS, the results were very encouraging. And given that terrestrial Rankine systems have efficiencies in the range of 30% or more, the Rankine system offers a way to achieve higher efficiencies with less radioisotope.

Mercury Rankine converters were baselined for the higher-powered U.S. SNAP-2 (3 kWe) and SNAP-8 (10–50 kWe) space nuclear reactor programs.

For the Rankine part of DOE's Dynamic Isotope Power System (DIPS) program, a lower temperature approach using an organic working fluid, Dowtherm A, was employed. The turbine inlet temperature was ~ 640 K and the overall system DC efficiency was over 16% which was over twice that of thermoelectric converters. Fig. 10 shows the organic Rankine DIPS and an illustration of how the unit could be assembled.

Stirling cycle

A Stirling engine operates by the cyclic compression and expansion of a gas. A free-piston Stirling engine (FPSE) produces electrical power by the linear motion of the piston (instead of the rotary motion of a Brayton or Rankine system) (Sundstrand Corporation, 1982). Over the years Stirling engines have been tested in everything from automobiles to an experiment converting the heat of a nuclear reactor to electricity (such as might be needed at a lunar base).

The Stirling engine is named for Robert Stirling who developed one in 1816. One of the key advantages of the Stirling cycle is that it is scalable from the lower powers (hundreds of watts or less) associated with RTGs to the higher powers (kilowatts to megawatts) for larger applications.

In the early 2000s, NASA pursued the development of an Advanced Stirling Radioisotope Generator (ASRG) that would provide ~ 140 We at beginning-of-mission and a specific power of 4.7 We/kg with efficiencies of 20% or more. For comparison, the ASRG could have produced almost as much power as the MMRTG but with only two GPHS modules versus the eight GPHS modules in the MMRTG. Electrically heated ground test units were built and accumulated tens of thousands of hours of operation. Fig. 11 is a cutaway diagram of the ASRG concept and Fig. 12 shows the components of the Advanced Stirling Converter (ASC) which is the "heart" of the ASRG. Fig. 13 shows the engineering test unit of the Advanced Stirling Radioisotope Generator.

As illustrated in Fig. 12, inside the ASRG, the oscillating piston and its displacer move in synchronization inside a closed, helium-filled cylinder. The displacer forces the helium gas to move back and forth between the "hot side" (heated by a radioisotope heat source module) and the "cold side" (which radiates to space). This back-and-forth movement drives the magnetized piston through the coil of wire more than 100 times per second to produce an alternating current of electricity.

Concluding remarks

A range of static and dynamic conversion systems is available or can be made available for radioisotope power sources/systems. These conversion systems will allow RPS to achieve higher powers for the same amount of radioisotope fuel or to use less fuel to achieve a given power. Furthermore, dynamic conversion systems lend themselves to growth to kilowatts and megawatts of power for the advanced exploration missions planned for the future.

Introduction

The use of fission reactors for power in space has been envisioned since the dawn of the nuclear era. During that time, a handful of SFP systems have been launched into space; one by the United States in 1965 (SNAP-10A) and several by the USSR (ending in the 1980s). Since then, several programs to develop space reactor systems have been pursued, but none have resulted in success. This encyclopedia chapter discusses the benefits and challenges of SFP systems. The following chapter in the encyclopedia investigates the historical efforts to develop SFP. The subsequent chapters then address the technology options that might some day be used to establish fission power in space.

The need for a robust power source in space

On Earth, life and humanity has relied on energy from the sun (plants, animals, organic fuels, heat, etc.), but in space you're essentially on your own. Power is the single most important element to the survival of both spacecraft and humans in space, and an abundance of power is essential to providing safe and reliable missions—without power there is no existence. For human exploration, the need for abundant power provides a different paradigm that we've come to know on Earth. A reliable supply of sufficient power is essential to the life of an astronaut, and much more important to their well-being than radiation risk from a reactor.

Power can be binned into three areas when discussing space exploration: electricity, propulsion, and heat.

Electricity is the most valuable asset that space power systems can provide. Almost all terrestrial technologies have evolved within the paradigm of available electricity, and with enough electricity almost anything can be accomplished. It is hard to imagine any spacecraft or human outpost in which electricity will not be the lifeblood of the mission. Nomads and Pioneers could live off the land to explore and settle the Earth; space explorers can potentially do the same thing sans one component: electricity. Some things can be done more efficiently without our favorite energy "middleman," but there is almost nothing we can't do if we have abundant electrical power. For near-term scientific missions, increased electricity allows more capable instruments, increased instrument duty cycles, onboard scientific analysis, higher data-rate communications, and smaller antennas. For human missions, abundant electricity enables science and exploration, but more importantly it is the foundation of human safety and life support.

Space Propulsion is the other required source of space power. The first order physics of space propulsion is very simple—throw something off the back of your spaceship and you will go faster (Newton’s third law of motion). In this respect, the brute force approach to space propulsion is to launch as much propellant as you can into Earth orbit, and if launch costs can be made affordable this is a great option for relatively low delta-V missions (like a conjunction class mission to Mars). If launch costs are high, and/or you need to get somewhere fast, then the key to making propulsion effective is to gain as much thrust as you can for every unit of mass that you eject (Specific Impulse or I_{sp}). On top of this, the thrust to weight of your propulsion system and spacecraft can be very important. Ultimately, a power source can provide a propulsion system in three ways: the byproducts of the power source are used directly as the propellant (direct propulsion), the power source provides heat directly to the propellant (thermal propulsion), or the power source creates electricity that is used to accelerate a heated/ionized propellant (electric propulsion). In all cases, abundant energy/power is needed to enable effective human space propulsion (with due concern given to the effort required to place those energy sources and propellants into Earth orbit).

Heat is needed to keep things warm and to drive chemical processes—these functions can be completed via electricity, but they are done more efficiently without it (because heat generally creates the electricity in the first place). In space, thermal heating is needed for systems ranging from the smallest spacecraft to large human outposts. Where adequate sunlight is not available, NASA has routinely used the Radioisotope Heater Unit (RHU) to keep components warm in space, while waste heat from a large thermodynamic power system could keep entire spacecraft or human outposts warm at essentially no “cost” to the infrastructure. Process heat is important to create practical and sustainable human outposts elsewhere in the solar system. Many technologies have been envisioned, and in some cases developed to transform in situ materials to usable consumables (air, water, rocket fuel) and/or construction materials (ceramics and metals). One of the most important and fundamental use of process heat may be to melt ice. Again, if a large-scale power system is used to create electricity, the process should reject enough “free” heat to meet many of these needs.

In the very long term, we would need to use in situ resources exclusively to power a sustained space-faring existence. These in situ resources could simply be the materials to fuel our previously developed technologies, or the in situ resource might provide a unique energy alternative (using site specific chemical or geothermic resources). In all cases, an Earth-based energy technology that can provide abundant power is needed to (1) get us to our destination and (2) establish a semi-autonomous outpost/colony which can eventually evolve to a self-sufficient location.

Advantages of fission over other power sources

Abundant power is needed to significantly explore and expand into space. A robust power source is needed that can provide high energy and power density while being independent of location, environment, and application. The primary energy alternatives that are available in the near-term are discussed below.

Solar power

Using the sun as an energy source in space is often the preferred option, but is limited in power density and is location specific; i.e., the sun can become a poor energy source if you’re ever in the sun’s shadow or in a dusty/cloudy environment, or as you move deeper into the solar system. Even on Earth, the sun is not practical as a source of baseload electricity. Solar power on the Moon is significantly hampered by the 28 day cycle (i.e., 14 Earth-days of darkness). The technology to efficiently and reliably store energy in the deep cold on the lunar night presents substantial challenges, and would likely be substantially more complex and heavier than the solar power system itself. On Mars, the diminished sunlight decreases the value of solar power, but it is the dust, and more importantly dust storms that make solar power unattractive. The potential of a protracted dust storm will require more baseload power and a longer term storage system, presenting the same challenges as a lunar system (in addition to the decreased solar insolation during the day). Finally, the lower power density of sunlight beyond the asteroid belt would make the required size of a solar powered system excessive for a high power mission.

Chemical power

Since the dawn of the human race, our favorite energy alternative to the sun has been to burn things (primarily wood until the industrial revolution). On Earth we are surrounded by materials laden in hydrogen and carbon, fortuitously surrounded by a gas that contains oxygen (air). When we move about, we generally worry about our fuel supply but take the oxidizer for granted, which is the heavier constituent. In space, we have to bring both fuel and oxidizer with us, or have a means of generating in situ (which requires power). Space does not change fundamental chemistry (except for gravitational effects on combustion), but using chemical power in space is extremely inefficient because of all the power needed to transport or create constituents in situ. In addition, storing these constituents in the extreme temperatures of space presents problems in logistics and reliability.

Energy storage

Energy-storage systems (e.g., batteries) have a role for almost any space mission, but generally only in the very early stages. The advantage of batteries is that we can use low-cost Earth-based technologies to generate the energy, and then extract it from the

storage technology to utilize it in space. There is considerable ongoing research in fuel-cells and alternative means of storing energy, which could be much more mass efficient than traditional batteries; however, there is no chance that a chemical-energy storage system would ever be practical to power ambitious space exploration. Energy storage is of course essential to many space power architectures, in particular solar power, but not as the primary power source, where the energy is launched from Earth. Some nuclear sources, such as anti-matter and even ^{238}Pu might fit within the definition of an energy storage system, but they are better classified as nuclear power sources.

Nuclear power

Nuclear power can be used to provide electricity, propulsion and/or heat in space. The major benefit of nuclear technology is that power can be provided in a robust form that is independent of location or application. There is a great deal of experience in space radioisotope power systems (Bennett, 2021), and limited experience in space fission power systems. On Earth, the physics of fission are well understood, and engineered systems are well established. Other nuclear power types like fusion, anti-matter, or options like triggered isotopes, are not well developed for either terrestrial or space application.

“Nuclear power in space” encompasses a wide range of sources, technologies and applications. The physical sources of nuclear energy that can be utilized are radioactive decay/transition, fission, fusion, and antimatter. The technologies to harness these forms of energy are almost limitless, but the list of practical near-term technologies is rather small. Various combinations of nuclear power sources, technologies, and applications can be used to enable our exploration and expansion into space. In the end, the attractiveness of nuclear energy in space is the ability to provide robust, long-lived, high power density (kW/kg) systems at any location.

The current forms of nuclear power that we know and can reproduce on some level are radioactive decay, fission, fusion and antimatter. In the table below $\text{LH}_2\text{-LOx}$ (liquid-hydrogen-liquid-oxygen) combustion is what is used in high performance chemical rockets (e.g., the space shuttle main engine), Pu-238 decay is used in radioisotope power sources (Bennett, 2021), $\text{D-}^3\text{He}$ fusion is the most likely space fusion power source, because it will be easier to utilize the energy (due to lack of high energy neutrons) and the potential ^3He inventory on the Moon, and antimatter represents the annihilation of a proton with an anti-proton (Howe, 2021).

Energy source	Energy density	Max. thermal power density
$\text{LH}_2\text{-LOx}$ combustion	13 MJ/kg	Limited only by engineering
Pu-238 decay	2,100,000 MJ/kg	0.54 kW/kg
U-235 fission	82,000,000 MJ/kg	Limited only by engineering
D-He3 fusion	354,000,000 MJ/kg	Limited only by engineering
Antimatter	90,000,000,000 MJ/kg	Limited only by engineering

The two key points of the above table is that (1) nuclear power sources offer enormously higher energy densities than chemical systems, and (2) that power density is limited for ^{238}Pu . Fission, fusion and antimatter can all provide energy and power densities beyond what we could feasibly utilize in the foreseeable future. However, discussions of fusion and anti-matter are essentially moot for decades or perhaps centuries to come, because even if we engineer the technologies required to make these power sources practical, we will not have the technologies to engineer the high power density systems needed for space application. Restated, fission has the ability to provide energy densities so high that it will take many generations of technology advancement (materials and fabrication) until we could take advantage of a higher energy density power source (even if that source itself was off the shelf). Therefore, since fission technology is established and well-understood, it is the obvious technology to focus on for space nuclear technology development.

It is possible that once we establish large scale settlements on Mars or elsewhere, that we could shift away from nuclear power to an in-situ source (geothermal power, solar power with an in situ panels and energy storage mechanisms, wind power where there is an atmosphere, or perhaps nuclear if we could mine thorium, uranium, D, He-3, etc.). Until then, we need to have a technology that can enable the energy intensive missions and operations that could get us to that end goal, and that power source is fission power.

Difference between space and terrestrial reactors

Space fission systems are significantly different from terrestrial fission systems, due both to the requirements and operating environment.

Things that make space reactor design more difficult than on Earth:

- Waste heat generated by a space fission system must be rejected via thermal radiation (except for a few surface power options), whereas terrestrial systems typically transfer waste heat to water or air. This difference results in a strong performance incentive to operate space fission systems at a higher temperature than their terrestrial counterparts.
- Most space reactor applications require the system to operate autonomously for the life of the mission with no maintenance, whereas terrestrial systems typically can be maintained/repared as needed. As space infrastructure grows over the decades, the opportunity for maintenance will grow, but the first generations of space fission systems will be mostly on their own.

- Space fission systems must be capable of: (1) being packaged into a payload shroud, (2) withstanding launch loads, (3) remaining safe during launch accidents, (4) self-deployment, (5) operating in zero or reduced gravity, and (6) surviving potential micrometeorite impacts.
- Low-mass is very important to space fission systems, and the performance of a space fission system often is measured in terms of its total mass (kilograms) divided by the kilowatts of power it produces (kilograms per kilowatt electric). This parameter (specific mass) is of little or no importance to terrestrial fission systems.
- Shielding requirements combined with the desire for low mass present issues unique to space reactors. On Earth many effective options are available, including plentiful supplies of dirt and water, heavy but effective structural materials like concrete and steel, and the potential to create significant distance/separation. In space, separation is limited, mass effective materials are important, and issues like thermal management and structural integrity (launch, landing, and operation) can be significant engineering issues.

Things that make space reactor design easier than on Earth:

- Space fission power systems will generally operate at power levels three to four orders of magnitude lower than traditional terrestrial nuclear power plants. This difference enables numerous design and control simplifications to be made, and allows long-lived reactors without refueling. First generation fission power systems might provide 1–30 kWe, and ultimately grow to 1–10 MWe power systems. Beyond 10 MWe the technology would probably no longer be considered a “space reactor”; i.e., it would probably look more like a terrestrial power plant. This is because (1) the need for such a high power indicates that a very robust infrastructure would already be in place, which could provide significant materials, excavation, assembly capability to construct a power plant and (2) the mass and size of the power system would eventually be bigger than a practical launch vehicle could bring from Earth.
- Terrestrial reactor design is focused on being able to meet rigorous safety requirements as demonstrated by consequence-based (dose-to-public) analyses of an extensive series of design-basis accidents (DBAs). Because space fission systems will not operate until they reach a high orbit, consequence-based accident analysis is mostly limited to launch and reentry accidents starting from a cold shutdown condition. As human presence increases, more attention will have to be made towards operational safety, but contaminations and environments issues should still be of less consequence.

These (and other) differences can result in different fuels, materials, and coolants being chosen for space reactors than are typically chosen for terrestrial systems. However, the infrastructure, experience, and trained personnel available from terrestrial use of fission technology are still of great use in the development of space systems.

Applications/benefits of space fission power

A key benefit of space fission power is its versatility, such that it can provide robust power for a wide variety of space applications.

Space power

Technically, any fission power source used off the Earth might be considered space power, but in this article “space power” refers to systems that provide electricity to spacecraft in the vacuum of outer space (in or beyond Earth orbit). Every reactor ever launched into space, either by the United States or USSR, has been in this class. The attractiveness of the space reactor versus other sources depends primarily on two parameters: power level and the availability of sunlight. Power levels $\ll$ 1 kWe are best provided by radioisotope systems, assuming that the supply/utilization of the radioisotope is not prohibitively expensive. Solar power is generally the best option inside of the asteroid belt, as long as the duration of eclipse is small and orientation can ensure that some of the solar panels always have a view of the sun. Therefore, the best use of space reactors is for missions where a power approximately equal or greater than 1 kWe is required, and the availability of sunlight is diminished by distance, eclipse, or attitude.

High power missions ($\sim$ 1 kWe or greater) to the outer solar-system are the most clear-cut applications for space reactors. Solar intensity drops by the square of the distance from the sun. Solar intensity is shown at various locations in the solar system in the table below.

	<i>Distance from sun (1 AU $\sim$ 1.5 e + 8 km)</i>	<i>Relative solar intensity</i>
Earth	1.0 AU	1.0000
Mars	1.5 AU	0.4328
Vesta	2.4 AU	0.1736
Ceres	2.8 AU	0.1276
Jupiter	5.2 AU	0.0370
Saturn	9.6 AU	0.0109
Uranus	19.2 AU	0.0027
Neptune	30.1 AU	0.0011
Pluto	39.5 AU	0.0006

Beyond the asteroid belt, solar power becomes very difficult: <4% of the solar intensity at Jupiter versus the Earth. Amazingly, solar technology has progressed enough to make the low-power (500 We) Juno mission (Bolton, 2017) to Jupiter practical. Thus at Jupiter, solar power competes well with radioisotope power, but at powers > 1 kWe fission should have an advantage. At Saturn and beyond it is hard to envision solar power becoming practical, so the trade will again be between radioisotope and fission.

Inside of the asteroid belt, with a clear view of the sun, the only time fission might make sense is at very high power levels ($\gg 10$ kWe). The reason for this is that the radiator of the fission power system will generally be much smaller than a solar panel array (for the same power). In this case the reactor might have an advantage in deployability and spacecraft maneuverability. The International Space Station (ISS) has a solar power array that provides a cycle-averaged output of ~ 100 kWe (> 200 kWe in direct sunlight) (Gibb, 2018); however, this array is massive and cumbersome. Another advantage of the relatively small radiator might be the ability to avoid detection, if desired. Solar panels reflect considerable sunlight and to work they have to face the sun; the ISS is brighter than Venus under the right conditions. A radiator does not have to face the sun, and generally will be designed not to in order to achieve maximum efficiency. The reactor is very hot, but it will be surrounded as much as possible by insulation to prevent thermal losses, such that the outer surfaces will be cool (and of very small profile). Nuclear radiation from the reactor might be detectable to spacecraft within 10s or even 100 s of kilometers by a highly specialized detector, but would be virtually impossible from 1000s of kilometers or from the surface of the Earth. The detectable distance would depend greatly on the reactor power and what fraction of radiation leaks from the reactor.

Currently, there are not many space missions under consideration that might require > 1 kWe in space (other than propulsion, which is discussed later). This is largely a chicken-and-the-egg dilemma—no one will design/develop a high power instruments or spacecraft because high power levels are not currently available, while no one will design/develop high-power power systems because no one is asking for them. While NASA science missions have been extremely successful since the 1960s, there has been no fundamental change in where we can go and how much power we have when we get there. We could increase the benefits of science missions by orders of magnitude with a robust, low-mass source of abundant power. The high cost and limited availability of ^{238}Pu also increases the future need for space fission power.

One of the key drivers for high power space fission systems might be communications. As more expansion into space occurs, around the Moon, Mars and beyond, there will be a need for a more bandwidth, which eventually might benefit from the high powers of a space reactor. For ambitious outer solar system missions, a high power source might be needed to signal strength. For all type of science missions, more power might be useful to provide more ability for interrogation, by offering high power/sensitivity sensors, probing signals (for subsurface mapping), ablative lasers, etc. Most importantly, there will likely be applications for high power that have not been considered yet. Many space scientists have focused their careers on trying to develop instruments that require 10s of Watts, instead of trying to envision instruments that use 100 s of Watts to kilowatts. This is partially because higher power instruments are generally heavier, but the recent reduction of Earth-to-orbit launch costs and the increased lift capability should alleviate that concern. Overall, it is likely that once abundant power is available, that people will find innovative ways to use it.

A typical space reactor configuration is shown in the figure below.

Surface power

The other major application of space fission power systems is surface power; i.e., power on the surface of any planet (other than Earth), moon, asteroid, or comet. Surface reactors could be the most practical near-term application of space fission systems, because of the difficulties of using solar power on the Moon and Mars. Fourteen days of darkness on the moon would require

substantial power storage if a solar-power system is used, including the ability to provide thermal heat. In addition, all of the concentrated and easier-to-process water of the Moon is in permanently shadowed regions; it might be easier to land a reactor there rather than try to deploy cables to a sunlit region. Mars presents a rather different challenge than the Moon. The length of a day (sol) is only slightly longer than an Earth day, so energy storage can be more practical. However, Mars is further from the sun (~ 1.52 AU). The solar intensity reaching Mars is $\sim 43\%$ that of the Moon (or Earth orbit). Mars also has a thin atmosphere which attenuates sunlight. The nominal optical depth ranges between 0.5 and 1.0 (depending on elevation, season and latitude), such that between 40% and 60% of sunlight reaches the surface. The biggest challenge is the potential for long-duration (months) dust storms, which can cause the direct sunlight to be reduced to $\ll 10\%$ of nominal, although scattered/diffuse light lessens the impact of the dust storm on solar panel output. This dust-storm issue requires several times more solar panel area/mass that would be required otherwise, and makes solar power more massive and complex than a fission power system. Surface power might also be of great interest on many of the moons in the outer solar system: e.g., Europa, Titan, Enceladus, Triton, etc.

Simple surface power systems could be the workhorse of the near-term human exploration infrastructure on the Moon, Mars, or other potential destinations (e.g., Titan, large asteroid). Some potential surface power electrical loads include habitats, in situ resource utilization plants, rechargeable rovers, construction equipment, and science experiments. The power output of a single workhorse surface system might be in the range of 10–40 kWe, with a lifetime of ~ 10 –20 years. In addition, the relatively low-power and “high” mass allowance of a surface reactor might make it the easiest space fission system to develop. For a human surface exploration mission, fission power has so many advantages over other power alternatives that the mass requirements will not be as stringent. This allows “mundane” reactor technologies to be used (i.e., stainless-steel, UMo fuel) at very benign power/flux levels, which makes development simple. Plus, as part of a “heavy” mission architecture there should be less programmatic pressure to meet mass targets, or worse, potentially decreasing mass requirements during development—a contributor to the downfall of the SP-100 program (Truscello, 1992).

The uses of electricity on the Moon, Mars, asteroids, etc. are vast. Nearly all technologies will be developed to run on electrical power, or off of another technology that uses electrical power (i.e., a pneumatic device would still use an electrically-driven compressor). There are several areas where abundant electricity are likely needed.

In situ resource utilization (ISRU): The ability to process materials that are available on-site (in situ) at your destination is essential to establishing a practical long-term presence anywhere in space. ISRU generally requires lots of power, and in most cases a lot of electricity. The most enabling aspect of ISRU might be rocket propellant production for return propulsion, assuming that a one-way existence is not preferred by most early space explorers and settlers. The rocket equation makes Mars missions extremely inefficient if you have to carry and land propellant on Mars in order to launch yourself back off of Mars. The ability to create oxygen from the abundant CO₂ supply may be the difference between practical and prohibitively expensive round trip travel to Mars (Zubrin, 1991). If a supply of hydrogen is available then both methane and oxygen can be made from CO₂ via the Sabatier reaction (Zubrin et al., 2013). The ideal situation would be to gain hydrogen from water/ice (which also would produce more oxygen), but early missions might bring hydrogen from Earth, since it is low mass relative to the oxygen. As the Moon, Mars, or asteroids become more industrialized, then power could be used to mine and process all of the materials required to sustain an infrastructure. The rapid advent of additive manufacturing, or 3D printing (Betzler, 2021) will make the effective utilization of in situ materials even more practical. Ultimately, if our capabilities in space become vast, then mining remote resources in space and returning them to Earth would be practical as well—there are several startup companies already hoping to do this, but it is probably many decades from potential profitability.

Life support: The first aspect of life support is tied to ISRU; i.e. the ability to create breathable air, drinkable water, and eventually an environment to produce food. The other aspect of life support is that most systems that maintain life support will be run by computers/electricity. Heating may not be electrical; it might be provided by “waste” heat from the reactor, or if the habitat is very well insulated (e.g., buried) then heat from the humans, computers, and appliances might be enough to keep the habitat warm by themselves. Overall, it is unlikely that it will be practical to develop a space life-support architecture that can operate without electricity, whereas this has always been very simple on Earth (although our lives become increasingly dependent on electricity every year).

Surface Transportation: Logistics dictate that electrically-powered vehicles will be the standard of transportation on the Moon or Mars. The rapid emergence of practical electrically-powered cars on the Earth makes this even more certain. Small fission reactors could create an ideal network of charging stations for mobility. A reactor would have a strong advantage over solar power in this application to allow transit on the Moon day-or-night, or to the “winter” side of Mars. For larger settlements, an electrically powered shuttle or trains would make sense: e.g., Martian Rails from the game Terraforming Mars (Fryxellius, 2017). In all cases, once a colony grows to a substantial size, the high power requirements for transportation will strongly favor a reactor.

Infrastructure and Habitat: Just as on Earth, everyday life on another planet/moon will use electricity for almost everything: lighting, construction, communication, science, exploration, refrigeration, computers, displays, entertainment, drilling, etc. The average household on Earth uses 2–3 kWe averaged over the course of the day, but can be much higher during peak demand. A remote isolated outpost would probably require more energy consumption. Considering all of the uses of electricity in this and prior paragraphs, it is reasonable to expect that the power system should be sized to produce 5–10 kWe per person on the Mars.

As human presence in space increases, then the economical paradigm would probably shift from “bring your power source with you” to “buy your electricity from an extra-terrestrial utility company.” This will happen similarly as it did on Earth, although there are still remote communities and mining operations that find it more economical to bring in their own power supply, instead of trying to connect to the grid.

A typical application of a surface power system and grid is shown in the figure below. The power systems shown are 10-kWe Kilopower reactors (McClure et al., 2020).

Power for nuclear electric propulsion (NEP)

Nuclear electric propulsion (NEP) utilizes space fission power to provide electricity for an electrically-powered thruster; the reactor for NEP is technically a space reactor, but is often considered in a separate class. In reality there would be very few differences between a reactor designed to power an electric thruster as opposed to a traditional spacecraft bus. In most cases the electricity would be used for both spacecraft power and propulsion, although the power conditioning (voltage, frequency) might be different.

The specific mass (kg/kWe) for NEP systems is generally much more important than for other space reactor applications, because of how system dry mass factors into the rocket equation. NEP reactors usually trend towards higher power levels because this generally lowers the specific mass, and because the thrust of electric propulsion systems tend to be low. Any bit of additional thrust (power) can be helpful in scenarios where trip time is limiting or the mission involves escape from a gravity well.

The best near term use for NEP is science missions to the outer planets. A recent study <ref-Casani> found that a 10 kWe NEP systems can enable numerous missions, including a tour that orbits (and deploys landers on) the Saturn moons Titan and Enceladus or a spacecraft that orbits Neptune and then its moon Triton and deploys a lander. The study also evaluates enabling missions to orbit Centaurs, Uranus, Pluto, and beyond.

Specialized NEP systems might also be of use in Earth orbit or cislunar space (any region between Earth and the orbit of the Moon) for missions to perform spacecraft maintenance, clean space debris/junk, or alter, maintain, or boost the orbits of satellites. An NEP system might also be used to help deflect an asteroid destined to hit the Earth, either to deliver an explosive charge or provide tugging force itself. An attractive option might be a gravitational tug, where the spacecraft constantly thrusts away from the asteroid at a force equate to its gravitational pull. The use of NEP for planetary defense will of course depend on the amount of advanced warning, and the power/thrust capability to adjust the orbit of asteroid/comets enough to miss the Earth. A high power, high specific impulse NEP system might also be needed for economical mining and transport raw materials from asteroids.

A high performance NEP reactor (> 1 MWe, < 10 kg/kWe) offers more potential benefit to long-term human space exploration than any other space reactor application. Whereas Nuclear Thermal Rockets (NTRs) offer a factor of 2 performance benefit over chemical rocket technology, a higher performance NEP system can offer orders of magnitude better performance (ISP)—a truly enabling and paradigm shifting technology. Advances are continuously being made in all of the non-nuclear technologies needed for an NEP system, most importantly power conversion, heat rejection, and thrusters. Significant advances are being made in ion thrusters and plasma thrusters, such that the deployment of high power EP systems appear possible within a decade or two. Conversely, a reactor for this kind of NEP system is essentially no closer to deployment than it was 50 years ago, just as NTRs are further from being flight-ready than they were 50 years ago. The difficulty in a high-performance NEP reactor is not achieving high power, but delivering power with a very low mass system, which requires very high temperature operation due to heat rejection requirements. It might require several reactor generations (technology evolution in steps) to reach performance levels for human

propulsion missions. This evolution can start with simpler space science or perhaps cargo missions, which will have simpler requirements but still provide useful performance for their application. The use of fission reactors for NEP is discussed in more detail in another chapter in this encyclopedia ([Morrison, 2021](#)).

Power for process heat

The use of thermal power for process heat is another potential application for space fission power; i.e., for heating, fuel production, ice melting, etc. In many applications, process heat might normally be provided by the waste heat from an electrical reactor power system, so technically the reactor would not be designed solely for process heat. However, there may be instances where thermal power is the primary requirement of a reactor; perhaps melting tough ice, producing chemicals via thermal processes, creating steam from Martian soil, etc., but even in those cases some electrical power conversion might be incorporated into the system design for bimodal use.

Challenges of space fission power

The need for low mass (high temperature)

To be useful or economical, a space fission system must have low enough mass to be launched into space, and in many cases transported to and/or landed at its final destination. The key distinction is low power system mass, as opposed to low reactor mass. In almost all cases, this requires a high temperature reactor, because most space environments do not have a thick atmosphere or bodies of water to provide an efficient heat sink. The efficiency of most power conversion technologies is rooted in the Carnot equation, or the ratio of the system hot-side (reactor) to cold-side (radiator) temperatures. If thermal radiation is used for heat rejection, the cold side usually needs to be ~ 400 K or higher (depending on sunlight, surroundings, etc.) to keep radiator size/mass reasonably small. This requires a reactor temperature of ~ 900 K to obtain reasonable thermodynamic efficiency, when taking into account various temperature gradients, losses from the core to the radiator, etc. If efficiency is too low, the need for heat rejection becomes a vicious circle; as efficiency drops, reactor power and radiator size increases, and the larger temperature gradients cause a further drop in efficiency, and so on.

A practical entry point for space reactor temperature is ~ 900 K or higher; this essentially precludes the use of water-cooled reactors, which is unfortunate because water-cooled reactor technology is highly developed. However, even if temperature wasn't a problem, water-cooled reactors would be troublesome for deployment in the cold temperatures of space (freeze/thaw issues) and for long-duration operation without maintenance due to chemistry concerns. Fortunately there are many existing reactor (fuel, clad, structure) that can provide power at ~ 900 K or higher—these are discussed in another chapter in this encyclopedia ([Poston, 2021a](#)). There are also several technologies to efficiently transfer reactor heat to the power conversion system ([Poston, 2021b](#)).

The need for low mass also requires materials to be mass effective. All other things equal, a space reactor design prefers: (1) Fuel-forms with higher uranium loading ($\text{U-metal} > \text{UN} > \text{UO}_2$) and pure fuel forms as opposed to particle or composite fuels

(e.g., TRISO, solid composites, etc.). (2) Structural materials with the highest strength to mass ratio in the desired temperature and irradiation environment. (3) Core materials (fuel, structure, neutron reflector, etc.) with low neutron capture other than fission. (4) Shielding materials with ability to scatter/capture neutrons with the lowest mass at modest temperatures.

The need for low mass sometimes dictates the use of materials that might be expensive or difficult to work with, for example beryllium as the neutron reflector or lithium hydride as the neutron shield (Poston, 2021c). Of course there are always exceptions to any of the above, and there is no single best material for space reactors in general (except perhaps beryllium). The combination of mass, power, temperature, stress, lifetime, cost, fabricability, availability, etc. must all be considered to determine the optimal material, but mass is usually one of the most important considerations.

The need for autonomy

Most space reactor applications will require the ability to operate reliably without any remote control or maintenance, especially for initial reactor generations before a substantial space infrastructure is established. Autonomous system control of some type is essential, because of the time delay between any space application and the Earth. Certain commands for startup and state changes could be given remotely, as long as a time delay is acceptable: seconds to the Moon, minutes to Mars, and hours to the outer planets.

The need for autonomous control places a strong emphasis on the ability to reliably instrument a reactor power system, and interpret and process the diagnostic signals. Solutions to these issues have been developed for reactors on Earth, but there are many issues unique to a space reactor. It is possible that some diagnostic instruments used on Earth might be too heavy, be launch sensitive, require too much power, have issues with extreme cold, or have trouble being packed close the reactor (irradiation and internal heating). On Earth, there is often the ability to replace faulty instruments, or interrogate instruments and determine if they are reading accurately, and perhaps recalibrate them. Also, terrestrial reactors generally have more room to include/attach diagnostics, more space to route cables, plentiful power, considerable floor space and shielding options for instrumentation racks, and no concern for mass. This allows terrestrial reactor designers to preclude most potential diagnostic issues by over-instrumenting the system; i.e., by providing enough diversity and redundancy to ensure the ability to get a reliable signal. If there are enough signals, especially if they are from diverse instruments, it is relatively easy to determine which readings are solid, which are reasonable, and which are bogus. In space, there will be diminished ability to any of the above.

The difficulty of ensuring accurate and dependable diagnostics is not the only instrumentation and control issue for a space reactor. The signals need to be interpreted and processed, and then commands must be given to control features, which must work properly upon command. The control computer must withstand radiation and have a thermal path to a heat sink to cool the components. One of the biggest concerns might be single event upset (SEP) caused by reactor radiation (mostly neutrons). Radiation hardened (rad hard) electronics exist for use in space, but they are generally designed without consideration of neutrons (e.g., they are hardened for solar radiation, galactic cosmic rays, Van Allen belts, etc.). The tolerance of many “rad hard” electronic components to neutron irradiation is unclear. The mitigation of potential electronic failure modes is redundancy, but this adds mass, power, cooling, and complexity concerns—the difficult question for any space reactors will be how much risk to take versus the “cost” of instrumentation and control redundancy.

The need for reliability

Many missions will only be practical with the use of only one reactor, thus the reactor power system as a whole represents a single-point failure. If a space reactor cannot be effectively designed with inherent redundancy, then components must be designed to be extremely reliable. The best path to high component reliability is to use proven technologies and design with large performance margins, but this often competes with the desire for low mass. Simplicity is another important factor that can reduce uncertainty and improve reliability. One of the biggest components that affects reactor reliability is the selection of cooling technology. A heat pipe reactor can offer redundancy, but might be more difficult to fabricate than a pumped fluid system, which is likely to have single point failures.

For human missions that rely on a fission power system, reliability is tantamount to safety. A loss of power in space or on Mars is likely a much bigger risk to astronauts than reactor radiation. This places reactors in a different paradigm, where more emphasis is placed on evaluating design basis accidents that impact system integrity, rather than radiation release. Another approach for human missions is to deploy several smaller reactors; i.e., if a mission requires 40 kWe, then deploy five 10-kWe reactors. This approach may be preferable, especially if it is simpler and cheaper to develop a 10-kWe reactor. This approach also provides more mission flexibility.

The need for long lifetime

For many applications, the best metric for the utility of a space reactor is probably energy (Joules), rather power (Watts), whether it be J/kg or J/\$. The costs of fabrication, launch, and deployment make it inefficient to frequently launch replacement reactors. This is true to potential surface outposts, long term orbital, cislunar missions, and high delta-V NEP missions (an optimal delta-V is best achieved with high J/kg system, depending on many factors). In these cases, lifetime is just as important as power. In addition, many deep space missions require long lifetime regardless, due to long travel times.

The desired lifetime of most space reactors might be measured in decades rather than years. This is no different from terrestrial power plants, except that there is no chance for refueling or replacing various life-limited parts. The desire for longer lifetime can exacerbate almost every engineering issue in the reactor: burnup reactivity swing (i.e., the deviation from criticality caused by fuel burnup), fuel performance (burnup related swelling or cracking), fission gas release, erosion, corrosion, mass-transfer/diffusion, creep strain, and irradiation damage (especially loss of ductility with dpa—displacements per atom).

The possible need for nuclear-powered system testing

Perhaps the biggest challenge to deploying a space fission power system is the potential need for a ground nuclear-powered test (GNT). Testing of new nuclear systems has become almost prohibitively cumbersome and expensive—this is surely part of the reason there has not been a successful new reactor deployed in the US for many decades. In addition, the testing of systems that operate in space presents other unique challenges. The combination of these two, nuclear and space, puts space reactors in an unfortunate class of their own. For a traditionally engineered system, the development approach can allow significant uncertainty in system performance, and a vigorous test program can be used to flush out performance issues and ultimately optimize performance (even for terrestrial reactors, as long as there is a chance to perform exploratory low-power reactor operations, and make subsequent changes, before extended full-power operation). This allows the design and development process to focus on what most view as traditional engineering: materials, procurement, fabrication, component development, and assembly. Alternatively, due to the cost and risk of testing, a space fission system must be designed so that a system “test” is in effect an actual “demonstration,” with as few uncertainties and unknowns as practically possible.

The primary purpose of a GNT would be to test the steady and dynamic performance of the integrated reactor power system. In most cases, other risks can be addressed in less expensive ways; e.g., nuclear lifetime risks are better tested in-pile in a test reactor, power conversion system risks are better addressed with electrically-heated testing, etc. The need for a GNT depends mostly on three primary factors. The first of these factors is how uncertain the performance of the integrated power system is. A GNT, and perhaps several GNTs are likely needed if a concept has complex and uncertain reactor dynamics; i.e. how the reactor power system will operate (e.g., startup, nominal operating states, transients, failure response, stability, nuclear burnup effects, etc.). Another measure of performance uncertainty is how similar the concept is to others that have successfully operated. The second factor that determines the need of a GNT is how hard it is to mimic coupled nuclear-thermal system performance with electrical testing. Heat-pipe-cooled reactors can often use resistance heaters to represent fuel pins, without disrupting the thermal-structural performance of the rest of the system, whereas high-pressure gas-cooled reactors may have great difficulty allowing penetrations (or remote coupling) for heaters without disrupting flow. The third factor that determines the need of a GNT is whether a fast-acting reactivity control system might be needed, which could only be adequately tested when coupled to a prototypic reactor.

Ultimately, the need for a GNT is a cost-benefit program decision that needs to be considered from the start of the program; i.e., can a concept be designed that meets the criteria in the prior paragraph; e.g., simple and predictable dynamics, electrically-heated system testing, and no need for a fast-acting reactivity control system. If these criteria can be met, then a GNT may not be desirable. If none of the criteria are met, the program might have to plan for numerous design, build, and test cycles to get the system to work adequately. Unfortunately, the more dependent a concept is on a GNT to resolve dynamics and control issues, the harder it will be to get regulatory approval for the GNT in the first place. A regulator will be much more likely to approve a test for a system with predictable and simple reactor performance, than one that is uncertain and complex. Another negative aspect of a GNT is that the test will not occur until near the end of the entire development program, and it is generally unwise to defer the majority of program risk until the end of a project.

Launch safety

As discussed previously, space reactor development is unique to terrestrial reactor development because the consequences of operational reactor accidents are diminished. However, space reactor deployment may become encumbered by potential safety issues that might result from launch accidents. All fission systems that use uranium fuel are minimally radioactive prior to operation. There is negligible radiological risk to the public if there was a launch explosion (or other accident) that dispersed all of the fuel material into the air (the radiation risk to on-site personnel would also be negligible) (McClure, 2021). The key to launch safety is ensuring that the reactor does not accidentally “turn on” (go critical and produce radioactivity) and subsequently provide a harmful radiation dose to anyone. Fission reactors are designed to achieve criticality with intentional/coordinated movements of control elements (to insert reactivity). Mechanisms must be engineered to ensure that the elements do not move inadvertently during any credible scenario; this is standard practice for every type of nuclear reactor, but space reactors have the additional issue of potential high speed impact and/or landing in the ocean. To simplify launch safety, most space reactor concepts are designed to preclude the possibility of inadvertent criticality during launch accidents, including water immersion.

Lack of progress and experience

Another significant challenge to deploying space reactors is not technical; it is the result of the poor track record of prior programs. There has not been a successful launch, or test of a space reactor system in the US since SNAP-10A in 1965 (Voss, 2021). The development of space fission power systems is indeed unique from any other advanced technology, and testing is extremely difficult, but

there is no reason why a simple, useful SFP system cannot be developed and deployed quickly (<5 years) and affordably (<<\$500M). Unfortunately, past programs in the US have gone too far in trying to develop advanced, higher performance reactors, and ultimately have failed.

Today, there is essentially no hands-on experience in the US for designing, building, and testing new reactors. There are a lot of capabilities to run codes and create conceptual designs, but limited ability to translate an idea into an actual engineering system. There is also no infrastructure for testing new reactors, or enough existing test reactors to obtain all of the needed fuel/material data for a novel reactor. Programs currently exist within DOE to address all of these issues, as there have been repeatedly in the past, but until a new reactor is successfully deployed it is unlikely that any significant capability or infrastructure will be maintained. The poor track record of prior space reactor programs is also making it increasingly difficult to convince potential users and funding agencies that a real program can be completed affordably.

Every year, advances in other technologies raise the bar (in terms of performance) for a useful first-generation space reactor. Other space power technologies (e.g., solar cells, energy storage, chemical rockets/cost) have been evolving to increasingly better performance over the past 50 years, while space reactor technology has been stagnant. Fortunately the entry point for fission still allows a rather simple reactor, but the more time that passes without a successful first-step, the more likely it becomes that the vast performance potential of space fission systems may never be realized.

The need for SFP technology evolution

It is clear from the “benefits” section above that SFP is needed to enable ambitious exploration and settlement of outer space. Power levels from kilowatts to megawatts can be provided at low mass and high reliability in almost any environment. It is clear from the “challenges” section that truly enabling SFP systems are very difficult engineer and deploy. Unfortunately, these challenges have continuously become greater over the years, as infrastructure and experience have been lost, nuclear testing more difficult and expensive, and other technologies have continued to evolve to better performance.

The key to breaking the cycle of SFP program failures over the past 50 years may be to start with a simple low power system; a system with perhaps some useful capability, but most importantly low development cost and risk. This was the impetus for the Kilopower reactor program (Poston, 2021d). Previous programs had tended to emphasize enabling performance over development risk, and all of them failed because they did not make sufficient progress within the touted cost and schedule. This issue was recognized decades ago by Admiral Hyman Rickover, in a letter he penned in 1953 concerning “academic versus practical reactors” (Rickover, 1973), and more recently in a white-paper concerning “real versus paper” reactors (Poston, 2020). The ironic consequence of this cycle of failure is that if any previous decision-maker had decided to go the simpler path in the past, we could already be on our 2nd or 3rd generation of reactors, which would probably have even much better performance than what they are shooting for now. Too many decision-makers are concerned about what they consider “dead-end” technologies; i.e., there is a specific aspect of an achievable, real reactor that will not get them to where they ultimately want to go. Another argument that was made in past programs was “if we’re going to invest in a big development program, we’d better get the technology we want.” This is a flawed argument because “big” is a strong function performance requirements. A high-performance system might have two or three times more development cost/risk than one with modestly lower performance. The real dead-end is never making enough progress to learn and build anything. Any technology that leads to a working reactor power system creates forward progress towards any and all highly advanced systems.

Summary

Space fission power is an enabling technology that will be required for humankind’s exploration and expansion into space. Solar and radioisotope power systems are very well suited for many potential uses, but many applications have been identified which will require fission power. The challenges of developing SFP are substantial, and have prevented the use of fission power in space over the past 50 years. This encyclopedia chapter identifies the challenges, and the promising benefits of FSP. The following chapters discuss what has been done previously, and what the options are to eventually unlock the vast potential of fission power in space.

Introduction

The importance of high energy, compact power systems for space was recognized in the early 1950s as the United States (US) began to consider developing satellites for reconnaissance missions. Fission power systems (FPS) were considered a primary candidate to power the early satellite missions. The US space reactor program began in the mid-1950s with the initiation of the Systems Nuclear Auxiliary Power (SNAP) program along with other nuclear development efforts such as naval reactors, Army Nuclear Power Program, Airplane Nuclear Program and nuclear rocket program—Rover/Nuclear Engine for Rocket Vehicle Application (NERVA).

Within the United States there have been multiple programmatic attempts to develop, manufacture, test and demonstrate in space a viable FPS, but the United States has only flown a single demonstration mission in 1965. Conversely, the Union of Soviet Socialist Republics (USSR) developed small compact FPSs that were successfully flown on over 30 reconnaissance missions and two advanced demonstration missions. Russia has since reported new efforts to develop higher power reactor systems (Zak, 2020).

While the US FPS program has not led to a viable space power system, the radioisotope power systems (RPS) has become a mainstay for National Aeronautics and Space Administration (NASA) missions. RPS are highly reliable, long-life low power systems (0.1–0.8 kWe). The perennial question is: why has the RPS program been so successful while after multiple attempts the FPS program has been stalled?

In this paper I will provide a short overview of the FPS programs followed by a technical summary of each program and their specific goals.

SNAP 1955–73

In 1951, the US Air Force (USAF) and Rand Corporation, requested the Atomic Energy Commission (AEC), the predecessor to the US Department of Energy (DOE), to study small reactors that could be used as power sources for early satellite systems (Perry, 1961). Based upon favorable results, the Rand Corporation recommended a small 2 kWe nuclear reactor as the baseline power for their proposed reconnaissance satellite program in their landmark study “Project Feedback” published March 1, 1954 (Lipp, 1954). In 1955 the USAF and AEC issued a formal request for proposals leading to the uranium-zirconium-hydride (UZrH) fueled design by Atomics International (AI). In 1957, the AEC took over control of the SNAP reactor program.

In 1958 through 1959, the USAF formally requested AI produce a SNAP system with thermoelectric power conversion (TE PCS) for a 0.5–3 kWe reconnaissance satellite mission. This led to the development of two systems: the 0.5 kWe SNAP 10A designed with a SNAP 2 reactor core at lower power with sodium-potassium (NaK) coolant, an electromagnetic (EM) pump with TE PCS and the 3 kWe SNAP 2 with a dynamic mercury (Hg) Rankine PCS. The SNAP 2 reactor mockup was completed in October 1957, the experimental reactor test began power operation in 1959 and the developmental reactor test began in 1961 (Jarrett, 1973). In 1960, the AEC and the AF jointly initiated the Space System Abbreviated Development Plan for Nuclear Auxiliary Power Orbital Test (SNAPSHOT) with the plan to complete four flights (JCAE, 1963). In 1963–64, the USAF mission was reoriented resulting in the cancellation of the SNAP 2 reactor development and the proposed SNAPSHOT flight tests. Development of the Hg Rankine PCS was funded through October 1966.

The Congressional Joint Committee on Atomic Energy (JCAE) recommended that the AEC fund the planned SNAP 10A flight as a technology demonstration mission. The SNAP 10A Flight System-3 (FS-3) was launched in April 1965 from Vandenberg AF base, CA and placed into a 500 nautical mile orbit. The system operated successfully for 43 days. The reactor permanently shut down due to what is believed to be a failure in the voltage regulator on the spacecraft (Berg, 1966). The ground test of the SNAP 10A flight system (FS-4) operated successfully for 417 days before the test was completed.

In 1959, NASA had a requirement for a 30 kWe and above space nuclear power system for nuclear electric propulsion (NEP) and interplanetary communication. NASA and the AEC established a joint effort to develop a higher power SNAP 8 FPS using the SNAP 2 technology with NaK coolant and an Hg Rankine PCS capable of providing from 30 to 60 kWe for up to 1 year of operation in space. Two SNAP 8 reactor tests were completed: the experimental reactor (S8ER) and the developmental reactor (S8DR) with integrated flight configuration. The S8DR testing began in June 1968 and shutdown prematurely in December 1969 due to an increase in coolant activity indicating a rupture in the fuel cladding. A large number of the fuel element cladding had cracks but the overall system performed well (AI, 1973).

The SNAP 50/Space Power Unit Reactor (SPUR) concept was developed by Pratt and Whitney (P&W), Canel, CT with a focus on higher power operation in the range of 300–1000 kWe for USAF or NASA NEP missions. The SNAP-50 was designed with uranium-nitride (UN) or uranium carbide (UC) fuel, refractory metal clad, lithium coolant and a potassium (K) Rankine PCS (P&W, 1962). The fuel and nonnuclear components were extensively tested under this program from 1961 through 1965 the component and subcomponent testing had been completed. P&W requested \$500 M for a ground test of a prototype and \$1B for a flight qualified system, and several billion more for a manned space flight in 1965 (AWST, 1965). In 1965, the program was transferred to the Lewis Research Lab (now NASA Glen Research Center) and converted to a long-term technology development program under the Advanced Liquid Metal Cooled Reactor (ALMCR) and Fast Power Reactor Program (Wahlquist and Voss, 1989). The SNAP 50 program was cancelled in 1968 with a total estimated cost of \$99 M 1968 dollars (Carwile, 1973).

Additional design and research efforts were focused on additional reactor technologies including the Advanced ZrH Reactor, Medium Power Reactor Experiment (MPRE), the 710 Gas Cooled Reactor, the Advanced Space Nuclear Power Program (SPR) and Thermionic reactor programs (Dix and Voss, 1984). There was a strong Aerospace Safety program that provided support to the SNAPSHOT program and SNAP 8 system design. Table 1 is a listing of each of the SNAP systems and their operating parameters.

As can be seen in Table 1 the program power goals increased over time from 0.5 to 300 kWe requiring higher temperature operation, more advanced materials, and higher PCS efficiencies. While the SNAP programs were successful in meeting many of the proposed goals it was not selected by USAF or NASA for specific missions leading to the program cancellation in 1973. The decision to develop different technologies and a range of power levels contributed to the programs cancellation. The total estimated costs through 1973 were \$730 M for all FPS technologies (Carwile, 1973) plus additional costs for operating, facility and equipment for a total of \$840 M (Dix and Voss, 1984) in 1973 dollars equivalent to around \$5B in 2020 dollars.

Interim studies and designs 1973–82

From the end of the SNAP program in 1973 through the early 1980s, research continued on space reactor designs and technologies. The government continued to grapple with identifying firm needs and requirements from NASA and USAF to identify clear path

Table 1 SNAP reactor system designs (Jarrett 1973, Staub 1973, Voss 1994, Asquith 1968, SNAP-50 Space Powerplant, 1962).

forward for space nuclear power (Dix and Voss, 1984). This led to the initiation of a small technology development program at Los Alamos Scientific Laboratory (now LANL) entitled Space Power Advanced Reactor (SPAR) to investigate a heat pipe reactor with TE PCS capable of producing 10–100 kWe (Buden and Angelo Sr, 1981). The SPAR system was designed to meet Department of Defense (DOD) requirements identified in 1977 including a 7–10 year lifetime in geosynchronous orbit and 3–5 years in low earth orbit with no single point failure. The DOD missions included space-based radar, surveillance, communications, orbital transfer vehicles using NEP and jammers (Boudreau and Buden, 1982).

SP-100, thermionic fuel element (TFE) and MMW 1982–94

In the early 1980s the decision was made to establish a joint DOE, DOD and NASA program to develop a 100 kWe space power system (SP-100). NASA selected the SP-100 for outer planetary missions using NEP and for planetary power. A Memorandum of Agreement (MOU) was established by the three agencies in November 1985 (Gebicke, 1992). DOE had the program lead and the Jet Propulsion Laboratory (JPL) had the project lead. The program was divided into three phases: 1983–85 Phase I technology and safety evaluation; FY1986 Phase II system design, technology development and testing, and ground test preparation, and Phase III a flight experiment (US Department of Energy (USDOE), 1988).

The SP-100 baseline design requirements were to provide 100 kWe for 7 years of full power operation over a 10 year lifetime with high reliability. It was designed to be launched within the space shuttle cargo bay (Manvi and Fujita, 1986). The original specific mass goal was 30 kg/kWe. Technology development goal was to ensure technology for lower power systems in the 10–100 kWe range up to the megawatt range by changing to a higher efficiency converter such as a Rankine system (DeMuth, 2003). A simpler set of requirements for an initial demonstration mission would have helped reduce the overall costs, size and system complexity.

A highly enriched uranium (HEU) UN fueled, refractory metal system with lithium coolant and TE PCS was selected as the primary system design. General Electric (GE) was chosen to be the primary system contractor and Hanford was selected for the nuclear assembly test (NAT). Throughout the program, from 1983 through 1994, a significant amount of work was completed on the system and components including: manufacturing and testing of 90 experimental fuel pins and the fabrication of 55,000 fuel pellets for the planned ground test (Matthews 1993; Matthews et al., 1994), mechanical and environmental testing of the control and safety drives (DeMuth, 2003), Nb-1%Zr and advanced Nb-1%Zr alloy, PWC-11, fabrication and qualification for the fuel clad and primary loop refractory material (Truscello and Rutger, 1992), advancement of thermoelectric conversion technology through design and testing (DeMuth, 2003), a gas separator concept, and design concepts an instrumentation multiplexer (MUX), thermoelectric electromagnetic (TEM) pump for startup and restart.

A thorough nuclear safety program was established for the SP-100 program with initial design guidelines that under accident conditions the reactor would remain subcritical, remain intact, and maintain physical integrity if there was a loss of coolant accident (LOCA) in space. With the demise of the DOD Strategic Defense Initiative program, the LEO mission was eliminated but the reentry shield remained in the baseline design as a precautionary measure to ensure the reactor would reenter intact and remain subcritical upon impact (Timme et al., 1993) and the LOCA loop was incorporated into the Auxiliary Cooling and Thaw (ACT) loop for startup and restart capability (DeMuth, 2003). Engineering mockup's of the reactor core were made at the Zero Power Physics Reactor at Argonne National Laboratory to validate the computer analysis. Fig. 1 illustrates the baseline SP-100 system as deployed in space.

The program was cancelled in the mid-1990s as the estimated costs to complete Phase II ground tests or to alternatively pursue a lower power flight demonstration were considered to be too high. Phase I technology review and down-select, and technology development cost approximately \$51 M in 1992 dollars (Gebicke, 1992). The actual funding for Phase II of \$438 M for 1986–1993 was significantly less than the amount agreed upon within the tri-agency MOA of \$768 M (Gebicke, 1992) resulting in an overall increase in the cost of the program and schedule extension.

Fig. 1 Baseline SP-100 system view in space.

Thermionic fuel element (TFE) development

In addition to the baseline SP-100 program, there was a joint DOE/DOD thermionics development program to demonstrate the technology readiness of a Thermionic Fuel Element (TFE) that could be used in an in-core reactor capable of producing 0.5–5 MWe at full power for 7 years (General Atomics (GA), 1994). The performance requirements for the TFE's included 9.3% efficiency, 4.1 a/o burnup for a 7 year lifetime using HEU uranium-dioxide (UO_2) (General Atomics (GA), 1994). A baseline design capable of producing 2 MWe was used for the sizing and operational requirements of the TFE's. A number of TFE with different materials and designs were tested in the Training, Research, Isotopes, General Atomics (TRIGA) test reactor providing operational data (General Atomics (GA), 1994). The program was later reoriented to the updated USAF power requirements in the 5–40 kWe range.

A total of \$37 M in 1992 dollars was spent on the TFE program (Gebicke, 1992) with the estimated cost to space qualify the system in 1992 was set at about \$451 M by the design contractor although DOE refuted the low cost estimate (Gebicke, 1992).

SDIO–MMW 1985–90

The need for megawatt-class power systems was recognized in 1984 with the initiation of the SDI program. Proposed SDI applications identified high power needs for directed energy weapons (DEW) and kinetic energy weapons (KEW) (US National Research Council (USNRC), 1989). Three modes of power were identified to support SDI mission needs (US National Research Council (USNRC), 1989):

1. Housekeeping Mode of kWe's, tens of kWe to hundreds of kWe continuous power for up to 10 years,
2. Alert Mode 100 kWe to up to about 10 MWe not easily defined but possibly up to a year or more, and
3. Burst Mode 10s to 100s of MWe and beyond for a few 100–1000 s.

In 1989, the MMW program received six reactor concepts and selected three for further evaluation during Phase II. The program was cancelled in 1990 prior to the start of Phase II, as the SDI program shifted priorities, due in part to the dissolution of the Soviet Union. In addition to the Phase I concept designs there was also a small amount of effort on fuel development (Buden, 1993).

Summary SP-100, TFE and MMW programs

The end of the MMW program in 1990, and the SP-100 and TFE programs in the mid-1990s illustrates the same issues that plagued the UZrH SNAP, SNAP-50/SPUR and thermionic reactors during the 1950s through the early 1970s and that is a lack of a clear mission, a continual change in the mission power level, and a diffusion of funding across multiple technologies and programs. In the end, the lack of focus, consistent funding and increased costs resulted in cancellation of all the programs. A clear US focus on a low power system could help end this pattern.

US/Russian Topaz II space reactor program 1991–95

The Topaz II program formally began in 1991 as a joint US and Russian team under the SDIO leadership with US participation including UNM, SNL, LANL, and the USAF. The program was initiated in 1989 when a team of Russian's attended the January 1989 Space Nuclear Power Conference in Albuquerque, NM and there was interest by a commercial firm to create a cooperate partnership (Nikitin et al., 2000; Dabrowski, 2013). The Topaz II space reactor was developed under the Soviet rule by the Central Design Bureau of Machine Building (CDBMB), St Petersburg and Kurchatov Institute of Atomic Energy (KIAE), Moscow beginning in 1969 (Nikitin et al., 2000). The system was designed to produce 6 kWe for 3 years using single-cell in-core thermionic converters (Voss, 1994). In 1989, there were multiple Topaz II units available for ground and flight testing. The Topaz II system had been extensively tested by the Russians including 12 thermo-physical tests, 4 dynamic tests, 4 static tests, 2 shock and vibration tests, 10 zero power tests and 6 full-up nuclear ground tests, but unlike its Soviet counterpart the Topaz I, it had not been flight tested (Voss and Rodriguez 1994).

The joint program consisted of three main parts: the Thermionic System Test (TSET) of a Topaz system using electrical heaters in place of nuclear fuel (Wold, 1992), the Topaz II flight experiment (Cameron et al., 1994), and thermionic converter test. Russian equipment was shipped to the United States in two separate deliveries: the first arrived in April 1992 with the complete reactor test stand and two ground reactor systems in an American military cargo plane to Albuquerque, NM and the second delivery of 4 Topaz II reactors in March 1994 via a commercial flight (Dabrowski, 2013; Nikitin et al., 2000). The United States had planned to purchase the already fabricated UO_2 fuel from the Russians for the flight demonstration. Estimated costs to complete the flight demonstration, excluding the cost of the launch vehicle was \$150M: \$80M for the satellite and \$70M for the power system (Gallup, 1992).

In all aspects of the Topaz II program, the United States and Russian participants worked closely together to achieve the technical goals. It was an unprecedented cooperative program that faced many cultural differences and yet was able to achieve many successes in testing and flight preparations. In October 1995 the program was transferred to the Defense Nuclear Agency (DNA), (now DTRA) as the SDIO program began to close down and the US government sold the Topaz II reactors back to the US contractor and returned to the Russian nuclear institutes as specified in the original contract. The program was terminated on March 19, 1997 and total program costs exceeded \$100M in 1997 dollars (US General Accounting Office (USGAO), 1997).

USSR space reactor program 1960–present

The USSR began development of FPS in the 1960s with the Bouk (Beechtree) FPS (Kukharkin, 2012). The Soviet Union had been using space nuclear power in space since 1970 with 32 launches of the Bouk 2.5 kWe reactor into LEU from 1970 through 1988 and two launches in 1987 of the more advance Topaz I thermionic system capable of producing 5–7 kWe for up to a year (Zakirov, 2011; Bennett, 1989). The Bouk and Topaz I were developed by the Red Star Institute and the Central Design Bureau for Machine Building (CDBMB). The reentry of Cosmos 954, a Bouk reactor, on January 24, 1978 resulted in the spread of radioactive material over a broad swath of Canadian territory resulting in a unique international legal situation between countries (Galloway, 1979). As a result of the Cosmos 954 accident, the Russian's spent several years redesigning the system to ensure the reactor would be boosted to a higher orbit at the end of life or eject the core upon uncontrolled reentry to ensure fuel burnup and dispersal in the upper atmosphere. Unfortunately the reactor systems launched after the redesign ejected their cores in higher orbit resulting in a significant increase in space debris.

Currently the Russian's are working on advanced FPS programs including a 150 kWe and 1.5 MWe Brayton system (Zak, 2020, Gabaraev et al., 2007).

Jupiter icy moons orbiter (JIMO)/Prometheus 2003–05

The Jupiter Icy Moons Orbiter (JIMO)/Prometheus project was a NASA program initiated in March 2003 and ended in October 2005. The initial program goals were to develop a nuclear power system capable of producing 200 kWe for 15–20 years in space with a proposed flight test in 2015 (Lehman et al., 2006). To meet the rather aggressive schedule the team chose a relatively low temperature reactor technology to meet the lifetime goals with high reliability. The program was initially managed by DOE but was transferred in March 2004 to Naval Reactors prime contractors (Ashcroft and Eshelman, 2006). The JIMO/Prometheus program initiated a comprehensive technology review and by the program end they had selected a conceptual baseline design based on a high temperature gas-cooled reactor with either UO_2 or UN fuel directly coupled to four Brayton engines with helium/xenon coolant (Ashcroft and Eshelman, 2006). An artist rendition of the lithium metal cooled reactor subsystem considered under the Prometheus project is shown in Fig. 2.

As the program continued, the costs estimates to meet the program goals increased significantly and lower power and shorter missions were considered. The program costs from 2003 through 2005 were \$463M in 2005 dollars (NASA, 2005) and the total estimated costs for a flight qualified systems was \$4.165B in 2005. Much of the high costs were driven by the long-life requirement, and the desire to complete a multi-year nuclear-powered test.

Fig. 2 Liquid metal cooled reactor subsystem design considered in the JIMO/Prometheus program (National Aeronautics and Space Administration (NASA), 2005).

Fig. 3 Mars FSP concept (Mason and Poston, 2010).

Fission surface power (FSP) 2006–07

The Affordable Fission Surface Power (FSP) was initiated by NASA in partnership with DOE in 2006 as the Prometheus program and JIMO mission was phased out (Mason and Poston, 2010). The project focused on developing FSP concepts operating from 10 to 100 kWe to meet lunar surface power needs, although the same technology could be used for Mars. The FSP was to produce 40 kWe with a low-risk approach to maintain costs to a reasonable level (Mason and Poston, 2010) by opting for “low risk, operational robustness, and affordability” (Mason et al., 2013). The reference design was a NaK cooled, UO_2 fueled fast spectrum reactor with Stirling power conversion and titanium-water heat pipe radiator (Mason et al., 2008; Mason and Poston, 2010). System operating temperature was 900 K (Mason et al., 2013). The system as it would be deployed on Mars is shown in Fig. 3.

A Technology Demonstration Unit (TDU), a nonnuclear system test with an external heat source simulating the reactor subsystem was tested in the 2014–15 timeframe in a vacuum chamber at NASA’s GRC. Component and subsystem tests were conducted prior to the TDU including the annular linear induction pumps, core simulator, and subscale and full scale Stirling engines (Briggs et al., 2016). The system simulated a single loop of the proposed 40 kWe FSP design with a primary pumped loop NaK loop transferring power from the reactor simulator to a single 12 kWe Stirling power converter and rejected heat to two pumped water loops (Briggs et al., 2016). The TDU as built produced 9.6 kWe at 18.4% efficient (Briggs et al., 2016); most of the system performed well, although the pump efficiency was very poor and was operated on facility power.

One of the impressive aspects of the FSP program, was their emphasis on early hardware testing and results. If continued, the program could have gone to an early flight demonstration and operation on the Mars surface. The 2010 FSP study estimated that the costs to develop, flight-qualify, and deliver a 40 kWe system to the lunar surface by 2020 would cost approximately \$1.4B with follow-on unit costs of \$215 M in 2010 dollars (Mason and Poston, 2010). If the FSP program had continued, it would provide a step-wise advancement of space nuclear technology from a low temperature system to a higher temperature superalloy or refractory metal system with UN fuel and dynamic power conversion thereby providing power in the 100 to 1 MWe and above range.

Kilopower 2013–18

In the early 2010s, the NASA Space Missions Directorate identified the need for a low mass 1–10 kWe space nuclear power system with a 10 year lifetime that would bridge the gap between RTGs and the FSP to enable deep space missions ([Mason et al., 2013](#)). A series of designs were evaluated leading to the down select of a solid cast uranium-molybdenum (UMo) fuel, with heat pipes on the outside of the core for lower power levels that directly transferred the heat to thermoelectric or Stirling engine power conversion system. The excess heat was transferred via water cooled heat pipes to the radiator system. The reactor was designed with HEU to maintain a small core and shield necessary for deep space missions. An artist rendition of a Kilopower system on the lunar surface is shown in [Fig. 4](#).

There were two primary reactor demonstration tests at the Nevada National Security Site (NNSS) Device Assembly Facility (DAF) facility in the Kilopower program: Demonstration Using Flattop Fissions (DUFF) test in 2012 ([Poston et al., 2013](#)) and Kilopower Reactor Using Stirling Technology (KRUSTY) 1 kWe demonstration ([McClure et al., 2020](#)). In 2016, a depleted uranium system was tested at GRC as part of the DUFF test series to develop the in-core heat pipe bonding and test the operation with electric heaters before completing the nuclear test at DAF in 2017. The KRUSTY test was done with a prototypical nuclear core and external heat pipes integrated to a Stirling system to demonstrate the system performance, load following capability and safety response. The KRUSTY system was designed, built and tested for \$18M in 2017 dollars, a fraction of the costs of other programs by choosing existing facilities and technologies, and maintaining a small focused team. After the completion of the KRUSTY test, the program goal was to design the flight unit and complete the first flight for an estimated \$150–\$250 M ([Palac, 2015](#)).

Later mission studies demonstrated that a 10 kWe Kilopower system could be used to provide power for the initial Mars mission, and a Kilopower systems was more advantageous than an FSP for a number of technical reasons ([Rucker, 2015](#)). Therefore, while Kilopower provided a low cost system for a 10 year lifetime at 1–10 kWe, it was not selected by NASA for continued development after the 2018 testing was completed.

Follow-on space nuclear: Fission surface power and megawatt NEP 2019–present

In 2019, the decision was made to transfer primary responsibility from NASA to DOE for a 10 kWe Fission Surface Power (FSP) system for lunar operations by 2027 with extensible operation on the Martian surface ([DOE/NE 2020](#)). System designs using high assay low enriched uranium (HALEU) rather than highly enriched uranium (HEU) are being evaluated as directed by Congress. The project is anticipated to kick off a design effort in early 2021. In addition, NASA and DOE are evaluating a high power reactor 1 MWe and above as part of a Nuclear Electric Propulsion (NEP) system.

Conclusions US space reactor program

The US space reactor program for power and NEP from 1960 to the present resembles more of a random walk rather than a clear and established technology program. Projects have been initiated to achieve power levels of hundreds of watts, kilowatts, tens of

Fig. 4 Artist's concept of Kilopower fission power system on the lunar surface ([National Aeronautics and Space Administration \(NASA\) News Release, 2018](#)).

kilowatts, hundreds of kilowatts and up to several mega-watts yet not a single program has moved forward into a viable space power alternative. Past studies and testing have included low and high temperature systems, moderated and unmoderated reactors, UO_2 to UN, stainless steel to refractory metals, static to dynamic power conversion, in-core and out of core power conversion, and many other variables. The biggest issue has been just selecting a simple first-generation technology and moving forward. As demonstrated in the Kilopower program, a low power 1 kWe system is approximately 10 times higher power than the current RTG for space power and would provide spacecraft designers a higher power option for deep space missions. Yet rather than building upon successes, the US program continues to stop and restart on a continual basis. Progress in this critical field will not occur until a step-wise approach is embraced similar to the RTG program.

RTC Reactivity Temperature Coefficient
SFP Space Fission Power
Slider Sliding Neutron Reflector
SS Stainless-Steel

Introduction

Space Fission Power (SFP) systems can enable ambitious exploration and human expansion throughout the solar system and beyond. Previous chapters in this encyclopedia discuss benefits and challenges of SFP (Poston, 2021a), and the history of past SFP programs (Voss, 2021). This chapter discusses several of the reactor technology options that could be used to overcome the challenges of space reactors. In this encyclopedia, Space Fission Power (SFP) systems, or space reactors, use the following definition:

SFP System (a.k.a. space reactor) = fission power system that can be launched from Earth.

The reason for this definition is to preclude discussion of future power plants that might operate in space, after industrial scale in-situ resource utilization and fabrication are established, or complex assembly capabilities might exist in Earth orbit. A space reactor is considered a mostly completed power system than must be light/small enough to be launched into space, and in some cases

transported and landed as well. As space architectures evolve the ability to use in-situ materials for shielding, heat rejection, or other components will gradually broaden this definition, but eventually the system will look more like a traditional power plant.

SFP Plant = fission system that requires significant construction/assembly after launch.

The practical upper power limit of a space reactor might be ~ 10 MWe; assuming a launchable mass limit of 100 metric tons (mT) and an optimal (near-term) power system specific mass of 10 kg/kWe. These are certainly not strict limits, rather they are round numbers meant to approximate practical limits for at least the next several decades. Anything of greater power is difficult to speculate about, because it will depend on what path that advanced rockets and space reactors follow to evolve to greater capability.

Technology options for space reactors

There are a wide range of technologies that can be considered for Space Fission Power (SFP) systems. The following section attempts to describe technology options independently of mission or application, which is not ideal because the selection of one technology often leads to a preference of another, and vice-versa. However, the alternative approach, i.e. describing classes of reactors and the combined suite of technologies that might best work for them, may be worse because black-and-white boundaries cannot be defined to include one technology and exclude another. The selection of reactor coolant and cooling technology is equally important to space reactor design, and is discussed in another chapter in this encyclopedia ([Poston, 2021b](#)).

Nuclear fuels

Choice of fissile material

The space reactor design process generally starts with the selection of fissile material; however, in almost every case this selection requires almost no thought; i.e. the best fissile material to use is ^{235}U . Uranium-235 is the fissile material loaded into almost every power plant and test reactor operating today. It is still relatively abundant and it is only slightly radioactive, which makes it economical for all reactor applications. Plutonium-239 is a possible fissile isotope that could significantly reduce mass of some systems, but would be more expensive to process, fabricate, transport, and assemble in a space reactor, create unique core chemistry and thermal concerns, and create significant operational safety and launch safety concerns. Uranium-233 can also reduce mass; it also has radiation concerns (from ^{232}U contamination) and the supply is very limited, although it might be easier to utilize in a space reactor than ^{239}Pu . Another issue with both ^{239}Pu or ^{233}U is a small delayed neutron fraction, less than half the value of ^{235}U . A smaller delayed neutron fraction introduces both operational and safety concerns. Americium-242 is another isotope that can offer low mass reactor cores, but is probably the less practical than ^{239}Pu or ^{233}U . Note that speculation about “better” fissile isotopes is only relevant for low power systems that could significantly benefit from lower critical mass. Lastly, thorium-based cores (i.e. ^{233}U breeder reactors) would be too heavy to be practical for SFP system, but could make sense for future SFP plants, especially if sufficient Th is found on a planet, moon or asteroid.

Choice of uranium enrichment

^{235}U is the obvious fissile material choice for early generation space reactors, which then leads to the question of enrichment. From a performance perspective the choice is very simple; highly enriched uranium (HEU), with enrichments $> 90\%$, will offer lower mass in almost every application. First order, the advantage of using HEU comes down to how “criticality limited” the “simplest” reactor option is, versus being limited by other design issues like heat transfer, swelling, strain, complexity, irradiation damage, mass transfer, etc. A criticality limited reactor generally has much more fuel than it otherwise would need to complete its mission, other than it requires “excessive” fuel to sustain a fission chain reaction (i.e. go “critical”). The distinction of “simplest” above is important because almost any reactor can move away from being criticality limited by adding enough moderation ([Poston, 2020](#)).

The negatives of HEU are almost all associated with proliferation concerns ([McClure, 2021](#); [Lal and Locke, 2020](#)); i.e. potential use of HEU for nuclear weapons. The US has regulations in place that allow the usage of HEU. These regulations restrict operations and require adequate security in order to prevent proliferation. This results in higher costs for certain aspects of development and deployment of HEU systems vs low enriched (LEU) systems. The definition of LEU within the regulatory framework is 20%, such that any fuel $< 20\%$ ^{235}U is LEU and any fuel $> 20\%$ is HEU. Clearly there is a huge difference in the attractiveness of 21% enrichment (enr.) and 93% enr., but they are effectively fall under the same requirements for protection. Therefore, most space reactors are designed to either 93% enr. (existing weapons grade material) or 19.75% enr. The specification of 19.75% is intended to give enough margin that no batch of processed fuel will end up at $> 20\%$ and thus violate the regulations. This enrichment level of 19.75% is commonly referred to as High Assay Low Enriched Uranium (HALEU), to differentiate it from the 4 to 5% enr. LEU used in commercial power plants (note that commercial power plants are not criticality limited – which allows for the low enrichment).

Ultimately, the performance benefit of HEU must be compared to disadvantages. In addition to the higher cost of operations, another disadvantage of HEU could be political. Even if the laws allow HEU to be used when properly protected, there might be resistance to using HEU depending on the policy stance of the government. The use of HEU might be considered a bad precedent

because other countries might try to establish a weapons program under the guise of establishing a space reactor program. The final decision to approve the use of HEU for launch in the US must come from the Office of the President, which adds programmatic risk. Another disadvantage of HEU could be availability and/or cost of enrichment. Currently this is not a factor, because there is no significant availability of HALEU, nor the ability to enrich it (it is actually created by downblending HEU). Commercialization of space reactors will probably be more difficult using HEU than LEU, and it is hoped that commercial production of HALEU will be available in the relatively near future.

Overall, it is hard to make a blanket statement about the pros and cons of HEU. The mass and/or simplicity benefit can be very substantial for systems that can enable a paradigm shift in space exploration, while for other applications the benefit of HEU will not outweigh the advantages of HALEU. The final decision will have to be made by the end-user or customer, based on their own cost/benefit assessment.

Uranium metal fuels

Metal based fuel, typically uranium alloyed with molybdenum or zirconium, can be very attractive for space reactor applications. The majority of reactors flown in space have used metal fuel (i.e. the Buk reactors of the USSR), and metal fuel has also been used in many terrestrial reactors. Metal fuels have many strong advantages over other fuels: ease of fabrication, high uranium density, and high thermal conductivity, but they do not perform well above 800–900 °C (depending on structural requirements) or with high nuclear burnup (> 1 a/o that is, fissioning of > 1% of initially loaded uranium atoms).

Metal fuels can be used to higher burnups, in fact they are intended to go to very high burnups ($\gg 10$ a/o) in advanced terrestrial reactors. However, the difficulty of ensuring fuel-pin lifetime would require significant testing. In addition, the high level of swelling with burnup reduces the uranium density to a point where it starts to lose its neutronic/mass advantage over other fuels, and the control system is required to accommodate the large reactivity swing caused by burnup.

<i>Metal fuel advantages for SFP</i>	<i>Metal fuel disadvantages for SFP</i>
- Very high uranium density - Very good thermal conductivity - Good testing history and database - Easy to manufacture with existing fabrication infrastructure - Good compatibility with liquid metals	- Relatively low peak temperature - Very high fuel swelling potential - Very high fission gas release potential - Poor chemical compatibility with steels and nickel-based alloys - Solid form phase-change potential

Metal-fuels (UMo or UZr) are almost always the best choice for space reactors that do not require fuel temperatures over ~ 900 °C, and are low enough power and lifetime to keep fuel burnup < 1 a/o.

Uranium oxide

UO₂ is probably the most robust and well understood fuel option for any nuclear reactor, as it is used in most commercial power plants today. Uranium oxide is often a euphemism for uranium dioxide (UO₂), although other oxide forms do exist (U₂O₅, UO₃, U₃O₈, UO₄). The sintering process to fabricate high density UO₂ pellets is well understood, and well as its neutronic and chemical behavior.

<i>UO₂ advantages for SFP</i>	<i>UO₂ disadvantages for SFP</i>
- Excellent testing history and database - Existing manufacturing infrastructure - Very high temperature capability - Relatively low swelling and fission gas release - Good stability and chemical compatibility with most structural materials	- Relatively low uranium density - Very low thermal conductivity - Poor compatibility with liquid metals - Brittle, low thermal shock resistance

UO₂ is the lowest-risk option for high power, high temperature, and/or long lifetime space reactors, and is often the best choice for any reactor that is not strongly criticality limited.

Uranium nitride

UN is a fuel that is perfectly suited for most space reactor applications, especially because of high uranium density and high thermal conductivity. Unfortunately, there is not a lot of existing infrastructure and data that pertains to UN; largely because UN has poor compatibility with water (and thus the vast majority of reactor experience). Uranium nitride was the baseline fuel for the SP-100

program, and ~200 kg of high-density pellets were successfully fabricated, via cold-press and sinter (Matthews et al., 1998). Irradiation data is limited, but this data plus corresponding analysis indicate relatively low swelling and fission gas release up to 6 a/o burnup. The melting point of UN is very high, but decomposition into free uranium and nitrogen gas has been shown to become significant between 1600 and 2000 K. Close correlations between performance (e.g., low swelling and fission gas release) and chemical impurities in UN requires careful fabrication pathways, adding to cost and complexity to beyond bench-scale facilities.

<i>UN advantages</i>	<i>UN disadvantages</i>
- High uranium density - Good thermal conductivity - Relatively high temperature capability - Relatively good chemical compatibility with most SFP structural materials and coolants. - Low fuel swelling and fission gas release	- Limited test and operation experience - Relatively difficult to manufacture - Limited fabrication capability - Need for nitrogen overpressure at high temperatures.

UN generally offers the best performance for reactors that require high fuel temperature ($\sim 900\text{ }^{\circ}\text{C} < T_{\text{fuel}} < \sim 1300\text{ }^{\circ}\text{C}$) and/or require relatively high burnup ($\sim 1\text{ a/o} < \text{burnup} < \sim 6\text{ a/o}$), and is the best choice for these reactors if a program is willing to take a slight risk (only risk until UN is successfully utilized).

Uranium carbide

Uranium carbide, UC or UC₂, were investigated heavily in the 60s and 70s, primarily as a fast reactor fuel, but did not find an attractive space reactor niche. The biggest problem with UC is swelling, and potential for runaway chemical reactions or swelling under certain conditions, while almost all advantages of UC are also realized by the better performing UN.

<i>Uranium carbide advantages</i>	<i>Uranium carbide disadvantages</i>
- Good uranium density - Good thermal conductivity - Good compatibility with liquid metals - High temperature capability	- Very high fuel swelling potential - Potential runaway reactions - Limited existing manufacture capability and experience

Uranium carbide does currently not appear to have a space reactor niche, unless a major fabrication and testing effort can establish that it is cost effective and can perform robustly.

Uranium-zirconium hydride

UZrH was the fuel for the only space reactor ever launched by the US – SNAP 10-A. The advantages of UZrH are due to the moderate effect of the hydrogen, which allows the potential for low mass reactors. UZrH is also a well understood fuel with a lot of experience and infrastructure (primarily in TRIGA type research reactors, Reese, 2021). It is usually not an attractive option for space reactors because relatively low temperature is required to prevent hydrogen loss, and it has rather complex swelling behavior.

<i>UZrH advantages</i>	<i>UZrH disadvantages</i>
- Excellent neutronics for low mass - Good testing history and database - Existing manufacturing infrastructure - High reactivity feedback mitigates accidental reactivity insertion scenarios.	- Low peak temperature - Limited lifetime (due to issues below) - Hydrogen loss can reduce reactivity - Fuel swelling rate can be high and is very sensitive to temperature

UZrH may have a niche for space reactors, but only applications with very short lifetimes ($< \sim 2$ years) and operate at relatively low fuel temperatures ($< \sim 750\text{ }^{\circ}\text{C}$).

Composite fuels

Composite fuels, or fuels that are mixed/integrated with other materials, represent a wide range of possible fuel technologies. Particle-based composites disperse small kernels of fuel within in a matrix of non-fuel materials. High temperature composites could use almost any fuel form (UO₂, UN, UC, UCO, etc.) and be dispersed into a wide variety of matrix materials (graphite,

SiC, BeO, etc.). The fuel particles are usually clad/coated with layers of graphite, ZrC, SiC, etc. The number and thickness of layers depends on the intended application. In traditional TRISO fuel (Helmreich, 2021), a SiC layer prevents fission gas release into the matrix, internal graphite layers isolate the SiC from the fuel, and an outer graphite layer protects the SiC during handling and fabrication. Composite fuels are not necessarily particle based. Some composite fuels disperse the fuel material in vein-like structures, while others attempt to create a uniform dispersion of fuel material, in what is referred to as a solid-solution.

<i>Composite fuel advantages</i>	<i>Composite fuel disadvantages</i>
- Very high temperatures - Very high burnup - High fission gas retention	- Low uranium density - Difficult to fabricate - Generally limited data and experience

Composite fuels are generally unfavorable for space reactors considered in this chapter (e.g. < 10 MWe). The low uranium density requires high mass or the complexity of heavy moderation. In addition, the benefit of fission gas retention is not as important for space reactors as for reactors on Earth.

Cermet fuels

If a ceramic fuel (UO₂, UN, etc.) is placed in a metal matrix it is referred to as cermet fuel (although it is still technically a composite fuel). In a particle-based cermet fuel, the fuel kernels do not necessarily use any coating layers, which allows the fuel loading to be higher than TRISO-type fuels. Cermet typically implies that a refractory metal like Mo or W is used as the matrix, but a stainless steel (SS) matrix could be included in the cermet family. If W is used as the matrix, then the reactor design will usually require HEU to have acceptable mass, whereas the mass can be acceptable with HALEU with an SS matrix, or perhaps Mo. The primary advantage of cermets is a high temperature limit and the ability to uniformly distribute heat due to high conductivity. The disadvantages are generally high mass and difficult fabrication.

<i>Cermet fuel advantages</i>	<i>Composite fuel disadvantages</i>
- Potential for very high temperatures - Potential for high power density core	- Relatively low uranium density - Difficult to fabricate - Limited data and experience

Cermet fuels are also generally unfavorable for the definition of space reactor used in this chapter (e.g. < 10 MWe). Their potential benefit is for very advanced high-temperature, high power reactors, which hopefully will be utilized several space reactor generations into the future.

Aqueous/salt fuels

It is very unlikely that a molten salt or aqueous fuel form will even be attractive for a space reactor, at least until a planet or Moon has very high power demands and substantial infrastructure. These types of reactors tend to be large in size and may require an online chemistry control system, plus they are gravity dependent. Once a large colony is established, then this type of reactor could have an advantage because of the ability to get very deep burns of nuclear fuel (i.e. extract more energy from limited fissile resources).

Cladding/structural materials

The choice of structural material is as important as the fuel selection, and in some ways more important. In this chapter, “structural” is meant to include fuel cladding, coolant boundaries, and core support. Cladding is the structural material that specifically contains the fuel. Coolant boundaries might be a pressure vessel, flow baffles, plenum, or heat pipe wall. Core support provides the internal structure to hold the entire core together.

In many reactors, the cladding, coolant boundaries, and core support are all the same materials; this is generally preferable, provided that the same material can provide all of the necessary properties. Other reactors can benefit by the use more than one structural material type, as long as they are not too dissimilar. Dissimilar materials often present problems due to concerns with mass transfer, differential thermal expansion, uneven wear, and fabrication concerns (e.g. the inability to weld, or perhaps 3D print). Most importantly, the fuel and cladding cannot generally be selected independently – the two must be chosen as what is referred to as a “fuel system.”

Like all space reactor choices, the selection of structural materials is made to provide the best performance (power, mass, reliability, surety) at the lowest practical cost and development risk. This decision is driven by a combination of factors, most of which can be included in one of the categories listed below.

Mechanical properties: A structural material must have adequate strength to prevent excessive strain or failure when presented with the anticipated primary and secondary stresses. Any particular reactor application might be limited by a combination of yield, ultimate, and/or creep strength. Another important mechanical property in most reactors is ductility, because the large changes in temperature generally create large thermal stresses that need to be relieved by thermal strain. Brittleness can be an important consideration for launch and landing loads. In some concepts, fatigue resistance can be important if vibrations are significant. Other concepts might prefer hardness and toughness to prevent erosion, although these parameters can make the material hard to fabricate. Ultimately, all mechanical properties must be accounted for (with margin) to create a practical engineering design. The mechanical properties at elevated temperatures are often the most important discriminator in terms of performance, because of how core temperature impacts system efficiency and mass.

Thermophysical properties: The most important thermophysical property of structural material is the coefficient of thermal expansion (CTE). The CTE usually plays a direct role in reactivity feedback (the change in reactor neutron multiplication with temperature), especially in compact, fast spectrum reactors. In many cases it can be the dominant reactivity temperature coefficient (RTC); e.g. in reactors where the structural material holds fuel pins/rods in place, either via a grid plate or a core monolithic-block. The structural expansion decreases reactivity by allowing more neutron leakage. It is generally favorable for the CTE to dominate reactivity feedback, because it is relatively constant with temperature, has less uncertainty than most cross section temperature effects, and can be accurately measured with repeated non-nuclear testing. The relation of the structural CTE to the fuel CTE is also extremely important for thermo-mechanical performance, because it affects gap sizes and can cause substantial stresses if mismatched. The importance of thermal conductivity depends on the specific reactor; high conductivity is very beneficial in monolithic-block reactors, but far less important in pin-type reactors. Specific heat can be important for transient behavior, but until a detailed design is completed it is hard to predict if a higher or lower specific heat is desirable.

Materials compatibility: The structural material must be compatible with the fuel, as mentioned previously with reference to the fuel system. At the same time the material must be compatible with the coolant, and in some cases the structure must create a mass transfer barrier between the fuel and coolant. One potential mitigating possibility is the use of a coating or liner. The coating needs to be compatible with both of the materials in question, provide a mass transfer barrier, and allow the reliable deposition/place-ment of the coating/liner. The use of coatings is becoming an increasingly attractive option as our ability to reliably apply thin coatings of materials improves. The problem with coatings is the ability to ensure long-life, and thermal-bonding if required, which can require length testing and potentially nuclear testing (some coatings can be damaged by modest levels of neutron fluence). For surface reactor applications the structural material also needs to be compatible with the environment; likely not a problem on the Moon, probably manageable on Mars, but a huge issue on the surface of Venus.

Neutronic properties: The ability for a reactor to go critical (sustain a fission chain-reaction) is the most fundamental requirement of any reactor. The neutron absorption cross sections (probabilities), and to a smaller extent scatter cross sections of the structure are a major consideration, especially in a moderated reactor. This gives unmoderated reactors an advantage because they have a larger suite of potential structural materials available. If possible, the ideal neutronic material would absorb minimal neutrons during nominal operation, and excess neutrons during off-nominal conditions (e.g. elevated temperatures, flooded accidents, etc.). The importance of neutron absorption goes well beyond the magnitude of the cross sections. The temperature dependence of the cross sections, and their effect and/or dependence on neutron energy spectrum plays a major role in the stability and controllability of the reactor.

Irradiation tolerance: Irradiation (exposure to reactor radiation) can affect both mechanical and thermophysical properties. In most cases damage is caused by neutrons. Fast, or high energy neutrons can damage the lattice structure and/or grain boundaries of a material and significantly change properties, often causing a slight increase in strength but a large decrease in ductility. Irradiation effects are often tied to the neutronic properties, e.g. a material for which neutron absorption can create an alpha particle (helium) can result in swelling and/or helium embrittlement. The level of irradiation damage is often a strong function of material temperature. In some cases high temperature exacerbates issues (e.g. swelling) while in other cases high temperature can mitigate issues (e.g. retention of ductility via annealing). The susceptibility to irradiation damage can be also strong function of how the material was fabricated and processed; i.e. how they affect lattice structure (phase), grain sizes, voids, defects, etc.

Material performance database: Most available materials have an existing database for mechanical and physical properties, but there are two aspects of space reactors that make this issue very problematic. The first issue that poses a problem is temperature. High temperature is needed for space reactors to achieve high power conversion efficiency (due to the difficulty of rejecting heat in space), more so than for most other existing engineering applications. Space reactors can also potentially experience very cold temperatures, well-below what most engineered system would experience. As a result, there is often limited or no performance data for candidate materials in the desired temperature regime (< 250 K and/or $\gg 1000$ K). The even more problematic issue is the irradiation tolerance of a candidate material. It is extremely hard to predict a specific material's sensitivity to irradiation. In addition, many materials have shown unique irradiation sensitivities which could never have been predicted without testing. A lack of required irradiation data for any specific material can present substantial cost and development risk for a concept. The lack of test reactor availability also makes this issue a major schedule driver. Until more test reactor capability becomes available, it is unlikely that a material that requires irradiation data would be selected for a near-term space reactor application. Either a material with

existing irradiation data will be used, or the neutron flux/fluence will have to be so low that the majority of materials experts would concur that it poses little damage potential.

Fabricability and infrastructure: The ability to physically produce the reactor is a non-negotiable requirement. The selection of structural material often comes down to the ability to successfully fabricate and assemble the core within acceptable time, cost, and risk. This generally gives common materials like stainless-steel (SS) an advantage over more advanced or novel structural materials. Just as important as the ability to make parts, is the ability to join them; a strong material is generally useless if it can't be welded or fabricated in a way to provide a hermetic seal. The emergence of additive manufacturing (3D printing) is a potential game-changer in this area (Betzler, 2021), because it could allow the manufacturing of more complicated and robust core components in the future, potentially even with refractory metals or even reactor fuel. The other consideration is the available infrastructure to reliability and consistently produce components, not just for the completed reactor, but very early on for the prototyping and testing that will be required. The level of existing infrastructure can have a major impact on cost and schedule of developing and delivering a reactor.

Mass density: For a space reactor, density is clearly one of the most important physical properties (in order to allow low mass), but it is listed last because it is rarely the basis for structural material selection. The selection is based on what material can best provide all of the above (strength, good thermal-neutronic characteristics, materials compatibility, infrastructure, etc.) at the lowest density. The density of the structural materials usually is not a major discriminator in system mass, as compared to the allowable temperatures, stresses, and surety that the material can provide. Only if the designer is lucky enough to have multiple candidates that equally meet all requirements, will density influence the selection.

Candidate structural materials

There are many possible structural materials. Traditionally, metals have been the material of choice for reactors (for many reasons), but advances in manufacturing of carbon-based composites and ceramics like SiC are making them increasingly attractive. All of the desired attributes listed above can quickly limit the list of structural candidates to only a handful of material types. Zirconium-based cladding is by far the most common structural material used in nuclear reactors, because it absorbs less neutrons than SS at thermal neutron energies. The neutronic advantage of Zr is rather small in most space reactors (because the neutron spectrum is less-thermalized), such that SS is preferred due to its higher ductility, ease of fabrication, and lower chemical activity at high temperatures (not an issue in space, but better for testing and potential use on Mars). The material choice for space reactors thus usually starts with SS, and then considers more advanced materials when only a higher temperature capability can meet requirements.

The table below gives a high-level, very-generalized view of structural metals from the design perspective of a space reactor. This table should only be used to perhaps decide what materials to further investigate for a trade study, because (1) the ratings have many caveats that would change for one concept versus another (e.g. with respect to fuel compatibility/experience), (2) advances in materials technology and testing might change the ratings (especially for SiC), (3) the ratings were developed by a reactor designer, not materials experts.

	SS	Ni-Alloy	Nb/Zr	Mo44Re	TZM(Mo)	W	SiC
Reasonable Temperature Limit	1000 K	1150 K	1400 K	1550 K	1600 K	1800 K	???
Fabricability	++++	+++	++	+	-	—	-
Experience /infrastructure	++++	+++	+	-	-	-	-
Materials database (incl. nuclear)	++++	++	+++	-	+	-	—
Cost	++++	+++	+	—	-	-	-
Availability (stock and vendor)	++++	+++	+	-	+	-	-
Cold ductility (launch/shipping loads)	++++	+++	++	+	-	-	—
Oxidation resistance	++++	+++	—	-	-	-	+++
Heat pipe performance, experience	++++	+++	+	+	++	-	—
Na and/or K compatibility	+++	++	+	++	+++	+	-
Density	++	+	++	-	+	-	++++
Thermal conductivity	—	-	-	-	++	+++	+
Neutronic performance (nominal)	+++	+	+	-	+	—	++++
Neutronics (water immersion)	—	-	-	+++	++	+++	—

Warning: do not rely on this table for design or technology decisions, use it only to perhaps guide what materials to investigate for a trade study. (1) The ratings have many caveats that would change for one concept versus another (e.g. with respect to fuel compatibility/experience). (2) advances in materials technology and testing might change the ratings (especially for SiC). (3) The ratings were developed by a reactor designer, not materials experts.

As mentioned above, do not rely on this table for any design or technology decisions (for the three reasons stated above), use it only to perhaps guide what materials to investigate for a trade study.

In the above table, the relative number of “+” (good) and “-” (poor) are meant as relative comparisons to the other materials. Neutronic characteristics are split into two categories: nominal is an indication of neutron absorption in the operating spectrum and

water immersion is how the change in absorptions might help mitigate accidental flooded criticality. The columns can be considered to represent a variety of materials, as listed below.

- SS = Stainless Steel: SS316 (hands-down the best combination of experience, data, and infrastructure), SS304 (usually lower mass if simpler requirements allow it), HT9 (only if extremely high fluence expected), oxide dispersion-strengthened steels (may be promising, but little irradiation data).
- Ni-Alloy = Nickel-Based Alloys: IN718 (probably the best combination of experience, data, and infrastructure), HastelloyXorN (frequently considered for reactors), Haynes-230 (great strength and infrastructure, limited irradiation data).
- Nb1Zr: Nb with 1w/o Zr is perhaps the easiest refractory metal to work with, and proposed for past space reactor programs. However, the potential for oxidation is a major problem during fabrication and testing (e.g. the need to test in a very strong vacuum).
- Mo44Re: Provide a nice combination of high temperature and manufacturability, but Re only neutronically practical in fast reactors.
- TZM(Mo): TZM is an alloy of mostly molybdenum (with small amounts of Ti, Zr, C), which provides higher strength and in some cases better ductility. TZM/Mo provide great strength and relatively good neutronics, but both TZM and Mo require special care to manage ductility concerns.
- W: Tungsten, or W alloys like WMo or WRe, offer great strength at high temperature; however fabricability, cost, and ductility all make it very difficult to design a reactor with, but can ultimately provide the temperature needed for future generations of low mass space power systems.
- SiC: Silicon carbide based materials, as a reactor structure, are the hardest material to rank on this chart, and the ratings should be taken even less literally than the others. Various forms of SiC (e.g. silicon carbide ceramic matrix composite) are gaining increasing attention and research because of its excellent potential performance. Perhaps in a few years a better comparison can be made. Other options in this class could include ZrC or carbon-carbon composites.

Core structural configuration

In addition to the choice of structural materials, there are various options that concern the general geometry and configuration of the core.

Grid-Plate: A grid-plate core uses a structural plate(s) to position and secure the entire lattice of fuel pins; likely cylindrical or hexagonal in shape, but not necessarily. This type of configuration is limited to relatively small reactor cores, partly because of spatial power variations that can occur in a large reactor (e.g. the need to change pin spacing or orificing of coolant flow rate in different regions of the core or enable to shuffle fuel.). The advantages of a grid-plate structure are the simplicity of construction and assembly, and the prior experience in designing and constructing pin-type reactors. The disadvantages of a pin-type structure are the potential for pin vibrations, geometric distortions (e.g. bowing), grid plate wear, relatively high void fraction (increases the potential for flooded criticality), and potential reactivity effects of relative fuel movements (including the potential for compaction of pins closer together via launch accident).

Monolith-block: A monolithic-block reactor core is effectively one solid piece; it could be fabricated as one piece, or pieces that are joined together to create the thermal-mechanical performance of a solid-block. In very low power reactors, the monolith can be the fuel itself, as for the Kilopower concept (Poston, 2021c). In most cases the monolith will be constructed from the structural material, and fuel, coolant, and potentially moderator are placed into holes within the monolith. In general, a monolithic-block concept provides the most robust design, which allows good prediction of fuel movements (reactivity feedback) and a solid conduction path between adjacent regions of the core (which are useful for decay heat removal and if there are failures in individual heat removal paths). The monolith block also has an advantage in launch accident safety because of the inability to compact the fuel pins closer together. The biggest drawbacks of using a monolithic-block are the potential difficulty of fabricating the block, and subsequently completing any required thermal or structural bonding requirements for the fuel, and potentially heat pipes and/or moderator (including numerous hermetic welds). The continued development of metallic 3D printing might make this option even more attractive.

Modular options: A modular option brings together several smaller assemblies to create the final core geometry; these assemblies can be either collections of fuel pins or smaller block-type sections. A modular-block design differs from a monolithic-block in that the core pieces are not physically bonded to each other. A modular-pin design uses fuel bundles or assemblies with smaller grid structures, instead of attaching all fuel pins to one large grid structure. The vast majority of terrestrial reactors use a modular collection of fuel assemblies, because their large size makes a monolithic or singular core impractical. The advantage of a modular option is almost entirely in fabrication; i.e. several smaller assemblies are easier to create than a single large one. A modular option also allows easier in-pile testing of components, and lessens the impact of an error during fabrication (e.g. it is less costly when damage occurs to one module as opposed to the entire core). The disadvantages of a modular approach is that it introduces additional complexity in many areas. An additional structural support subsystem is required – essentially a grid-plate structure for the modules. A modular option also adds potential negatives and uncertainties in performance. Movements of modules with respect to each other can create unwanted gaps or concentrated stress points. These movements create additional reactivity feedback mechanisms and potentially create unique flooded criticality configurations (e.g. if they become dislodged). A modular approach can also increase mass due to the need for additional gap tolerances and/or structural material.

Neutron reflection

Neutron reflectors have a very important role in space reactors. A good neutron reflector can:

- Allow the reactor to achieve criticality at lower fuel and system mass.
- Flatten the fission power distribution to decrease peak temperature and burnup.
- Provide shielding of the core radiation to help reduce shield mass.
- Reduce the potential power spike of criticality accidents.
- Provide enough neutronic worth to allow simple external control.
- Allow high temperature operation and good heat transfer when needed.
- Allow a fail-safe option to preclude launch accident criticality.

Fortunately, one natural material exists that does all of the above very well – beryllium. Beryllium has low mass density, high neutron scatter, low neutron absorption, has high thermal conductivity, and can tolerate relatively high temperatures. No other material comes close to the benefits of beryllium; in fact space reactors might not be very attractive without it.

The only significant negative of beryllium is the potential health issue of berylliosis. Only a small fraction of the population is sensitive to beryllium, but those that are can develop a very serious chronic lung condition. Modern fabrication facilities incorporate many precautionary measures and have greatly limited exposure to workers, but this is an issue that must be considered for operational safety and potential accidental exposures, including launch accidents. The other negative aspect of beryllium is that it is relatively expensive (partly because of the health measures that must be followed in order to use it), but this expense is not likely to be a major fraction of a space reactor budget (whereas on Earth, the health and cost issues might outweigh the benefits of beryllium). There are many other potential materials for the reflector (silica, alumina, magnesia, boron-carbide (enriched in ^{11}B), diamond, etc.), but it is highly unlikely that any of these would be preferable to beryllium (unless a reactor could ultimately use in-situ reflector materials at its final destination).

There are two forms of beryllium that can be used as a neutron reflector: beryllium metal (Be) and beryllium oxide (BeO). The metal form is easier to fabricate and is a much better structural material (less brittle). The ceramic form, BeO, can potentially operate at higher temperatures (depending on structural requirements) and is create more neutron reflection. Oxygen packs tightly within the BeO lattice such that the material has a higher number density than Be, and oxygen has even high scatter cross section than beryllium. A relative comparison of Be and BeO is listed below.

<i>Advantages of Be</i>	<i>Advantages of BeO</i>
- Lower mass density	- Higher macroscopic scattering
- Easier fabrication	- More chemically inert
- Better structural material	- Higher temperature potential
- Higher conductivity at high temperatures	- Higher conductivity at low temperatures
- Less potential for cracking, swelling	- Better shielding effect
- More neutron moderation	- Less neutron moderation

The last row may appear to be a contradiction (i.e. “more” or “less” can both be an advantage), but there are some reactor concepts where an influx of moderated neutrons is beneficial, while in others it is a problem. Beryllium metal provides increased moderation because of lower atomic mass, and also because neutrons that return to the fuel incur more net scattering events (neutrons travel further out into the lower density reflector, thus have a smaller solid angle to return directly to fuel).

On a mass basis the two options, Be and BeO, are often rather similar to each other. The BeO reflector is thinner, but the lower density of the Be balances the mass (depending on many factors). The lowest mass option can depend on the reactor’s preference for moderated neutrons, depending on the level of isotopes that absorb neutrons in the fuel and/or structure. The biggest discriminator between Be and BeO is sometimes the reflector effect on power peaking. The goal of the designer is generally to have the same fuel power density on the edges of the reactor as in the center. If a Be reflector makes the core edge power density too high, then BeO may be preferred, and vice-versa. The goal of a space reactor design is to minimize system mass, so the shielding effect of the reflector also plays a major role. Structural mass must also be considered, which sometimes gives Be an advantage because it can better offer its own structural support.

Thermal management is another major factor that affects the choice of reflector material. The conductivity of both Be and BeO are very good, but vary differently with temperature; the preferential conductivity profile will depend on the differences between nominal and decay power heat transfer. The potential for BeO to crack is a thermal management risk, while the higher possible temperature of BeO (depending on other factors) can create a thermal management advantage.

The final discriminator between Be and BeO is irradiation damage potential. Both materials can undergo significant swelling under the right conditions. Beryllium metal is generally more resistant to irradiation swelling than BeO. There is relatively little swelling in Be at fast neutron fluences $< 1\text{e}21 \text{ n}\cdot\text{cm}^{-2}$, regardless of temperature. If fast neutron fluence exceeds $1\text{e}21 \text{ n}\cdot\text{cm}^{-2}$ the Be temperature should generally be kept below $\sim 800 \text{ K}$, to prevent swelling and He embrittlement. Beryllium oxide exhibits the opposite temperature dependent behavior; swelling is much greater at lower temperatures than at higher temperatures (due

to an annealing effect). At temperatures >1000 K swelling is rather small up to $1e21$ n/cm² and even higher. At temperatures <500 K swelling is very high at fluences as low as $2e20$ n-cm⁻². Another possible negative of BeO is that most of the irradiation data is based on older grades and manufacturing techniques; “modern” BeO might exhibit different behavior and/or require more testing.

Practical space reactor designs are most likely to be cylindrical, which generally simplifies fabrication, control, heat removal, etc. To be mass effective, these cylindrical designs will usually utilize a radial reflector (around the outer circumference of the core) and axial reflectors (at top and bottom). In general, the axial reflector region will operate at high temperatures and also be in contact with other high temperature materials (fuel, spacer, structure, etc.). Therefore, BeO is usually the best choice for the axial reflectors, given the high temperature capability and chemical inertness. In addition, BeO is usually good choice for the axial reflector because it can play a better role in shielding. Sometimes, a design will use a thicker axial reflector on one end versus the other, due to shielding requirements, or to tailor the axial power distribution if desired. The radial reflector region is usually much larger (more mass sensitive) and more difficult to thermally manage. The higher scattering of BeO can be advantageous because it can allow smaller thickness, and this reduction in shield radius can reduce system mass. Although, if the reflector can be kept cool and power peaking on the core edge is low, then Be can have an advantage.

All of the above issues make the choice between Be or BeO rather complex, and frequently the optimal selection is not which material provides the lowest mass based solely on a criticality basis. A real engineering design is usually required to make a proper selection.

Neutron moderation

The reactor neutron spectrum is one of the fundamental design choices for any fission reactor. Many times the decision is presented at the highest level as fast versus thermal neutron spectrum. In reality, the decision is whether to use any special means to modify the spectrum, which can result in an energy spectrum anywhere between fast and thermal; although, in a compact space reactor it is difficult to achieve a truly thermal spectrum. For the purpose of this discussion “unmoderated” will be used interchangeably with “fast,” even though an unmoderated TRISO reactor may not be considered fast. A “moderated” system refers to a reactor that uses specific low-Z materials to slow down (moderate) neutrons to lower energies than would otherwise be seen in an unmoderated reactor with the same technologies. Reactors that use UZrH or carbon-based fuel, and/or use water cooling are inherently moderated, whereas externally-moderated systems will position moderator separate (heterogeneously) from the fuel.

The two most attractive candidates for external moderators are generally ZrH and YH, because they can provide high hydrogen density at relatively high temperatures; ZrH can potentially operate up to 950 K, while YH can perhaps go as high as 1100 K. These limits are general and should not be used as design limits for any particular reactor; they depend greatly on the desired hydrogen ratio, the effectiveness of coatings/liners to prevent hydrogen loss, the ability to stay within a temperature range to discourage swelling, and enough margin to prevent overheating due to uncertainties and potential transient conditions. Other hydrogenous materials like LiH (enriched in ⁷Li), water, polypropylene, etc. are generally unattractive because they would require significant cooling within the reactor. Beryllium and graphite can potentially be used, but they are relatively ineffective in the small geometries required for space reactors.

The following paragraphs discuss the pros and cons of fast versus moderated systems for space reactors.

Mass: At first glance, a moderated system appears to have a significant mass advantage over a fast system. This is because the fuel inventory can be reduced substantially (assuming the same enrichment is used) and the fuel accounts for a significant fraction of space reactor mass. The actual mass savings would depend on how well the moderating material (most likely hydrogen) could be placed in the core geometry; if the reactor could be made more compact, the use of a moderator could also save significantly on reflector and shield mass (although moderated reactors are often larger in size, not smaller). A moderated system has a lower neutron flux (because the fission cross section is higher) and a smaller neutron-leakage fraction, both of which can help reduce neutron shield mass. Alternately, the gamma shielding mass of a moderated system can be higher because it generally has less dense material in the core than a fast system. As mentioned earlier, the most important contributor to system mass is temperature, so even though the reactor and shield might be physically lighter for a moderated system, it may not provide a lighter spacecraft if the temperature is lower. Another factor is that a moderated system is likely to have more uncertainty and development risk than a fast system, which increases the probability of upward mass creep during development.

Thermal performance: In a very small reactor, only hydrogen can be an effective moderator (hydrogen slows down neutrons far more efficiently than any other atom because its mass is essentially the same as a neutron, which maximizes momentum exchange due to conservation of energy). The primary difficulty of using hydrogen or a hydrogenous material is desire for high reactor temperature. There is no established technology that can hold hydrogen at temperatures >1100 K for a long period of time. The other option is to attempt to cool the moderating material, which adds a new level of complexity to the reactor system and would add substantial risk in cost, schedule, and reliability. Adding a second cooling mechanism, whether pumped or heat-pipe driven, and integrating it into the system would be very difficult. Another factor that could limit the potential for a moderator to save mass is if the reactor were heat-transfer limited. If the same fuel enrichment were used (which would be the case if mass reduction was the goal), then the power density would be higher in the moderated reactor, which may not be acceptable in a heat-transfer-limited system.

Nuclear performance: There are considerable neutronic differences between fast and moderated reactors. In a moderated system, the neutrons undergo many collisions before absorption, which adds significantly to the neutron lifetime, especially as its velocity becomes slower. The difference in neutron generation time between the fast (microseconds) and moderated systems (milliseconds) is great, but the overall effect of this difference is minor. Neutron lifetime could impact system stability and levels of overshoot and undershoot of powers and temperatures, but these differences will generally be small. The only condition where short neutron lifetime could present a problem is if a scenario arose where prompt supercriticality was achieved. Moderated systems could have an advantage in prompt insertion accident, but unmoderated systems generally require much less excess reactivity, so they might have a lower probability of experiencing a prompt criticality. Moderated systems also have much larger temperature reactivity feedback coefficients. This is considered to be a major advantage in a terrestrial power plant because the large negative feedback is effective in preventing overheating in many accident scenarios. Preventing core damage during overheating is not a major safety concern for space reactors, so this advantage is diminished.

Conversely, large feedback coefficients create a significant problem during start-up and shutdown because considerably more excess reactivity is needed to sustain criticality from the start-up temperature and operating temperature. Moderated reactors also usually require more excess reactivity for reactivity loss due to fuel burnup. The need to add significant reactivity during startup increases the chance of large power swings occurring while trying to bring the reactor up to temperature. One factor that could mitigate the need for excess burnup reactivity is the potential to use burnable poisons to reduce burnup reactivity loss; although the moderated system is starting at a disadvantage in this respect if it uses less fuel for the same power level. In addition to the potential complication of higher-temperature feedback, a moderated system has additional feedback mechanisms (moderator temperature and potentially others) and the behavior of the temperature feedback is more complex. A fast space reactor is simpler because it receives almost all of its temperature feedback from physical core expansion, which generally provides simple, monotonic feedback. Also, there is more of a spatial dependence of reactivity feedback in a moderated system because of the shorter neutron mean free path. This dependence not only makes reactor behavior more complex but also makes simple point-kinetics calculations and simple testing techniques less valid.

Lifetime: The impact of moderation on system lifetime is dependent on many factors. If system lifetime is limited by fast fluence, then the moderated system has an advantage because fast flux will be lower; although this is application and technology dependent, and fluence does not appear to be a life-limiting factor for most potential space reactors. If system lifetime is limited by fuel burnup, then a moderated system will lose the potential mass advantage that is gained by using less fuel. To have a competitive mass, a moderated system must have considerably less ^{235}U inventory than a fast reactor; therefore the moderated system loses a larger fraction of its fissile material with burnup. Also, a moderated system will be much more sensitive to the build-up neutron absorbing fission products. Perhaps the biggest lifetime issue might be moderator lifetime itself (possibly hydrogen loss), which would depend on the technology selected for moderation and the means to ensure it stays cool. All of the effects require more fuel to overcome, but also increase the uncertainty in achieving the required “nuclear” lifetime, versus a very predictable fast reactor.

Complexity: The complexity of a moderated system is much greater than for a fast system at almost every level. Some of these factors have been discussed previously, such as the potential need to develop and integrate a moderating cooling system and the fact that the neutronic behavior of a moderated system is more complex. Any added complexity propagates through the entire program, through design, development, fabrication, analysis, testing, and system integration, thus significantly adding to program development risk.

Safety: All space reactors must be safe; the discriminator in safety is how much effort and difficulty there is in ensuring that the system is safe. As mentioned previously, the only significant nuclear safety concern is inadvertent criticality. The fast system should have two advantages in this area. First, the fast system requires less excess criticality because of the temperature defect (change in reactivity from ambient to operating temperature). The reduced excess criticality results in a smaller reactivity change between nominal and flooded conditions, which is an easier condition to meet. Second, given the nature of the material neutron cross sections, a faster spectrum can take better advantage of intrinsic spectral safety. Core materials can be used that have very low cross sections in the fast-spectrum region but moderately large cross sections in the epithermal region. If a thermal system could be designed to be fully or overly moderated, it would have an advantage, but this is probably impossible for this size of reactor. Another advantage of fast space reactors is the ability for the radial reflector to have very large reactivity worth; this simplifies operational safety because it is generally much harder to find any scenario where the fuel would go critical during nominal or accidental operations.

Safeguards: Safeguards is essentially the only area where a moderated system has a clear advantage. It can use a lower quantity of ^{235}U —either less HEU or potentially a lower-enriched fuel. A lower inventory of HEU is probably not a significant safeguards advantage because safeguards would have to be treated similarly (there is no possibility that the volume of HEU could be reduced to the point where protection requirements became less stringent). The only potential advantage of a moderator is that it offers the potential to provide a lower mass system the uses of HALEU, but there is a difference between low mass on paper versus an actual built reactor, which was discussed earlier.

Cost and development risk: The only significant cost advantage of a moderated system would be fuel security and handling costs, if it could use HALEU where a fast system could not. However, almost all of the other factors mentioned favor the fast system as being lower cost and easier to develop.

The table below gives a high level look at the relative merits of moderated and fast systems for space reactors. Unless safeguards becomes the predominant issue or a low-mass spacecraft application can be found at lower reactor temperatures, the fast system

appears to be the best choice. Although, this is a highly generalized view – it is hard to make a blanket statement about the use of moderations without considering the specifics of an application.

	<i>Moderated</i>	<i>Fast</i>
Fuel mass	+++	
Reactor mass (including shield)	++	
Power system mass	+	
Thermal performance/simplicity		+++
Neutronic performance/simplicity		+++
Lifetime		+++
Testing effort		++
Safety effort		++
Safeguards effort	++	
Cost and development		+++

Reactivity control

Reactivity control for most reactors is achieved by physically introducing/removing a neutron poison material into/from the core; although many other methods are possible: e.g. creating internal voids, poisoning the coolant, introducing moderator, etc. The compact size of space reactors allows for the option to control the reactor externally versus internally. Internal control is what is typically used for terrestrial reactors, i.e. control rods or elements move within the fueled region. External control utilizes elements that move outside of the fueled region; this method of control used for some small test reactors and all successfully deployed space reactors.

Internal control

For most space reactors, internal control (control rods or blades) is generally not desirable unless sufficient reactivity worth cannot be obtained with external control. This is because internal control elements provide more difficult system integration, including penetrations through the reactor vessel (if applicable), disruptions in the core structure/lattice, additional in-core structure, and thermal management concerns. Thermal management can be a major issue, because the poison will have a higher power density when inside the core and the heat removal path from the poison may be difficult and/or uncertain. The additional heating and irradiation damage also increases the possibility of bowing or distortion, which increases the possibility of a stuck element.

In cases where even more reactivity worth is required (or lower mass is needed), the internal rod can contain a length of poison “followed” by a length of material that serves as a reflector, moderator and/or fissile material (as opposed to a void). The use of a “follower” can increase reactivity worth significantly (thus lower mass), but exacerbates all of integration/heating issues. The power deposition in the follower will make it run hotter than the fuel; such that a fission follower is very problematic (unless active cooling of the follower can be easily and reliably provided). In addition, the length of the rod is twice as long (which makes alignment more difficult) and requires storage length on both sides of the reactor. The use of a follower often looks very good on paper, but it should not be selected unless a full engineering design can justify it.

Like all of the discussions in this encyclopedia, the above statements are generalized. There may be cases where internal control not only provides low mass, but also provides the simplest option. The use of internal control can be ideal for very small, low-power reactors without a pressure boundary, e.g. Kilopower.

External control

Poison Control Drums: The most common option for external control is the use of rotating cylindrical control drums. One side of a control drum contains a material with strong neutron reflection (e.g. Be or BeO). The other side contains a material with strong neutron absorption (e.g. B₄C, Hf, etc.). Reactivity is increased by rotating the poison material away from the core, and vice-versa. General nomenclature defines control “drums in” as the shutdown condition, in which the poison is closest to the core. Control “drums out” defines the maximum reactivity condition, in which the poison is furthest from the core.

Leakage Control Drums: Another form of control drum uses void, as opposed to poison as the method to decrease reactivity. A segment of the cylinder is “removed,” delineated by a circular chord. When the voided portion of the cylinder is closer to the core there is more neutron leakage (lower reactivity), and vice-versa. In a high L/D reactor, the least reactivity position might be when the drums are partially rotated, to give the core a direct view of space. In low L/D reactors, the least reactivity position might be when the drums are fully rotated such that the voided area is all closest to the core.

Sliding/Moving Reflectors: Another option for external control is to physically move the neutron reflecting material away from the core. Reflector segments (sometimes referred to as “sliders”) can be translated or slid axially along the core perimeter, exposing part

of the core to a voided leakage gap. This technique usually provides more reactivity worth than any other external control option, because of the high radial reflector worth of compact reactors. Another similar option is to pivot reflector segments outward like flower petals or an umbrella; this option removes the system integration issue (if the segments fan outward but stay within the shield cone angle), but does not provide nearly as much reactivity worth as sliders.

Poison Shutter Control Elements: External reactivity control can also be achieved by a thin annulus (or other shape) of poison material that slides like a shutter between the core and reflector. Usually, this method does not provide enough reactivity worth to satisfy all neutronic requirements, unless the returning flux from the reflector is highly moderated (which is generally not an attractive design option). The only practical use of the poison shutter might be as a launch safety mechanism, because the poison will be much more effective in a flooded reactor state than the nominal state.

The options above represent the four combinations of the following two choices: absorption vs leakage and rotation vs translation. Each choice comes with specific disadvantages. Some of the relative disadvantages of absorption vs leakage are listed below.

<i>Absorption/poison control disadvantages</i>	<i>Leakage/void control disadvantages</i>
- Generally less reactivity worth, higher mass - Additional material/component required - Heat removal path needed from poison - Burnup of poison isotopes diminishes worth	- Radiation leakage is major shielding issue unless a pure shadow shielded application - Gaps create a thermal short circuit from core, causing major variability in power balance - Reactor criticality affected by surroundings

The disadvantages of using a poison are all rather small issues, except for heat removal and perhaps burnup in a very high power/flux reactor. The radiation issue caused by leakage control is essentially a showstopper for any application that requires radial shielding, or any surface application. The power balance issue is also a significant engineering issue, typically much more problematic than any of the issues listed with using a poison.

Some of the relative disadvantages of rotation vs translation are listed below.

<i>Rotating drum control disadvantages</i>	<i>Translating control disadvantages</i>
- Generally less reactivity worth, higher mass - Azimuthal power variations with rotation	- Potential for very large axial power peaking - The need for space to withdraw elements creates system integration and shielding issues - Long non-cylindrical elements with asymmetric heating may be more prone to bowing or distortion - Potentially more issues with alignment, bearings, gravity and power requirement - Perhaps more likely to move into fully reactive position with accidental impact - Change in center-of-gravity with movement

The only significant disadvantage of using rotation is mass. The azimuthal power peaking of rotation is generally less of a concern than the axial power peaking of translation, plus as seen above translation introduces several potential issues.

The issues discussed above usually lead to the selection of poison control drums for reactivity control, unless mass is of the highest priority.

Control redundancy and diversity

In terrestrial reactors, control redundancy and diversity are generally required to ensure safe shutdown (although this is not always an absolute requirement). Redundancy implies that at least 2 independent options for shutdown exist and diversity implies that at least two different types of shutdown mechanisms exist.

For a reactor that operates in space, the ability to shutdown will not present a significant safety issue, so the need for redundancy and/or diversity is mostly a reliability issue; unless astronauts are nearby, but even then, the reliability of their power source is probably more important to their well-being than radiation release. Regardless, if control drums are used it is likely that only 1 or 2 of them would have to operate to shut down the reactor. The only area where redundancy and/or diversity might be important to space reactor safety is to prevent the inadvertent withdrawal of control elements, which could be provided through redundant interlocks or features that prevent motion without a controlled initiation. Some space reactor control reliability issues are: whether to incorporate reactivity margin for the reactor to operate if 1 or 2 drums are stuck in the shutdown (drum in) position, whether to gang control elements together or keep them independent, whether to include a redundant control motor for each drum/gang, etc.

Summary

There are a wide variety of technology choices for space reactors, although in some cases the required performance (e.g. temperature, lifetime, mass) reduce the number of practical choices to a relatively small number. The fuel and structural material choice must be

made in tandem, and also consider the selection of coolant (which is discussed in the next chapter of this encyclopedia). All technology choices must attempt to balance system performance (e.g. mass, power, lifetime, reliability, etc.) with the cost and risk of successful deployment (e.g., design, development, procurement, integration, testing, safety, etc.).

Introduction

Space fission power systems (space reactors) can enable truly ambitious space exploration and a permanent human presence beyond Earth orbit. Earlier articles in this encyclopedia discuss the benefits and challenges of space reactors (Poston, 2021a) and the history of space reactor development and deployment (Voss, 2021). Other articles present the technology options for space reactor core technologies (Poston, 2021b) and shielding (Poston, 2021c), while this article discusses the options for core cooling technology. The discussion and comparison of these technologies separately is not preferable, because for any specific space reactor application the selection of each technology cannot be decoupled (i.e. they are dependent on each other). However, at the highest level this article can provide a general comparison of various cooling technologies.

Power conversion assumptions

The only way to adequately compare reactor cooling technologies is when they are coupled with power conversion systems (PCS). For this comparison a power in the range of hundreds of kilowatts thermal is assumed. At this thermal power level, there are two likely near-term candidates for power conversion—Stirling and Brayton. Thermoelectric (TE) power conversion is certainly viable, but its relatively low efficiency usually makes it unattractive at high power levels, because the reactor must produce (and the radiator must reject) substantially more thermal power. A TE PCS might still be attractive at low powers ($< \sim 10$ kWe) if high reliability is valued over mass, provided that a sufficient quantity of qualified thermoelectrics is available. There are numerous other power conversion options that could be considered, but are generally considered either lower performance and/or less mature for operation in space: e.g., Rankine, thermionic, AMTEC, thermophotovoltaic (TPV), magnetohydrodynamic (MHD), etc.

The comparison between Stirling and Brayton is not straightforward. In many cases Stirling engines are a better choice than Brayton systems, because of generally higher efficiency, and perhaps more options for redundancy (due to smaller unit sizes). Stirling converters also may be more attractive for surface applications, because gravity can be used to make coupling to the Stirling engines more simple and reliable. However, Brayton systems have the experience of a large commercial terrestrial infrastructure for

turbo-machinery. Also, the mass of Brayton systems tends to scale much better at higher power than Stirling engines. A very rough, simplified rule of thumb might be that Stirlings are preferred below 50 kWe and Braytons are preferred above 100 kWe. Clearly, this rule of thumb depends greatly on the specific application, and also on technology development; e.g., there is current research involving low power Braytons and high power Stirlings, either of which could change the balance.

As noted above, the comparison provided is generally directed at a power level of 100 s of kWe, which leans the discussion towards Brayton systems and allows a direct-gas-cooled reactor to be considered more favorably. Wherever possible, statements are caveated to indicate how technologies and trades might be impacted by power level and/or PCS technology.

More information about dynamic power conversion, specifically Stirling versus Brayton, can be found in (Mason, 2013). A discussion of heat transport and power conversion for the Kilopower and KRUSTY reactors can be found in Gibson et al. (2020). There is also a very good discussion of potential heat transport and power conversion technologies in Angelo and Buden (1985).

Core cooling options

The three most commonly considered means of cooling a space reactor are:

- Gas cooled,
- Heat-pipe cooled, and
- Pumped-liquid-metal cooled.

There are many other options, including natural convection, liquid fuel, conduction-only, water coolant, organic coolant, internal boiling, etc., but these are usually found to have either poor performance and/or require significant technology development.

Each of the three common power removal technologies are introduced in following sections. In each section, a representative schematic of the reactor and core are shown. Each of the concepts shown in Figs. 1–3 are preliminary ~500-kWt conceptual designs for the Jupiter Icy Moons Orbiter (JIMO) program (Poston et al., 2004). These reactors were all designed to use uranium nitride fuel and were intended to power a 100 kWe Brayton PCS for 12 years.

Gas-cooled space reactors

A gas-cooled (GC) reactor is the simplest choice for core cooling—the same working fluid for the Brayton system can also be the coolant gas for the reactor. The basic flow layout would have the working fluid emerging from heat rejection system (HRS), being compressed by a compressor using the shaft power from the turbine, flowing through the reactor and heated, performing work as it expands and passes through the turbine and then back to the HRS for cooling. This system will have very simple plumbing, with a single compressor/turbine (although a multi-staged turbine could be considered), and one or more simple heat exchangers (a recuperator is almost always desirable to improve efficiency).

The core flow channels will generally be larger than for a liquid metal system, because the gas will have a lower heat transfer coefficient and lower heat capacity. The gas will need to be at a high pressure (to enable heat transfer) which can increase the stresses and structural mass. The gas boundary will also represent a single point of failure. In summary the system is very simple, but that simplicity comes with some increased weight and potentially lower reliability. Some of these concerns can be reduced if

Fig. 1 Gas-cooled JIMO reactor concept.

Fig. 2 Heat-pipe-cooled JIMO reactor concept.

Fig. 3 Liquid-metal-cooled JIMO reactor concept.

a super-critical CO_2 reactor/Brayton can be developed, but in the near-term coolants like He, HeXe, HeKr, or standard CO_2 appear more likely.

A gas-cooled space reactor concept has never been developed, but it was selected as the baseline technology for the JIMO program shortly before its cancellation (Donald, 2005). The GC concept was selected as the baseline (for a higher power 200-kWe system than the ones shown) mostly because it would be quicker to build and test, with the backup being the heat pipe reactor (which was preferable for reliability reasons, but a HP reactor had never been build and tested at the time). A more recent study of gas-cooled Mars surface reactors can be found in Poston and McClure (2019).

Heat-pipe-cooled space reactors

Heat-pipe-cooled (HP) reactors have approximately tens to potentially thousands of heat pipes bonded to the reactor core, which transfer heat out of the core using passive physics. In a heat pipe, power enters the evaporator region to boil the working fluid (which is a liquid metal in the high-temperature heat pipes used for space reactors). The resulting pressure build-up causes the vapor to travel (limited by the speed of sound) to the colder end (condenser) of the heat pipe where it condenses and transfers heat. The

condensed liquid is then brought back to the evaporator of the heat pipe via capillary forces. The capillary force is generally produced by a wick of metal screen, but can also be provided by grooves or slots. Gravity can aid or deter fluid flow depending on orientation—a heat pipe that uses only gravity to drive flow is generally classified to as a thermosiphon. This method of heat transfer (boiling liquid metal) is so efficient that the heat pipe can remain close to isothermal (constant temperature) from the evaporator (hot end) to the condenser (cold end), even if several kilowatts are being transferred over the length of the pipe.

Heat pipes used as primary heat transport will have a heat exchanger (HX) on the cold end of the heat pipe to transfer the heat to the power conversion system; although this HX can be as simple as a conductive or radiative interface. For a Brayton system the HX will transfer heat to the working fluid, which is the gas that will be circulated to the Brayton system. The plumbing for the working fluid might look similar to a gas-cooled reactor except that the gas is heated in the heat pipe/gas heat exchanger instead of directly inside the core.

An HP reactor core is typically smaller than the gas core, since boiling liquid metal in a heat pipe moves more heat much more effectively. Heat pipes also have the feature of being able to incorporate several independent HXs attached to their condensers, thus allowing for more redundancy in the system and potentially increased reliability. In Fig. 2, heat pipes exit vertically from the “top” of the reactor, and run straight through three independent gas HXs.

Heat-pipe-cooled space reactors have been considered since the invention of the heat pipe (Grover et al., 1964). Early designs were proposed by Koenig and Ranken (1977) and Houts et al. (1995), and more recently the Kilopower reactor, which was successfully tested in Poston et al. (2020).

Pumped-liquid-metal-cooled space reactors

A pumped-liquid-metal-cooled (LM) space reactor generally uses a low-density, low-melting point fluid such as sodium, potassium, sodium-potassium eutectic (NaK), or lithium. Space LM reactors require a mechanical or electromagnetic pump to circulate the liquid metal through the core to an HX and then back to the core. Natural circulation could be considered on the Moon or Mars, but it is extremely unlikely that natural convection could provide enough power to justify the mass of the reactor. The HX heats the working fluid gas used by the Brayton system; thus, much like the heat-pipe-cooled space reactor, the heat exchanger is the heating portion of the Brayton circuit that produces power. An LM reactor can have multiple heat exchangers to increase the reliability of the system, and can be easily integrated with Stirling, TE, or other power conversion technologies. Fig. 3 shows a lithium-cooled reactor concept that uses annular linear induction pumps (ALIPs) to circulate flow.

Liquid-metal-cooled reactors often produce the smallest reactor core, since liquid metals have very high heat transfer coefficients and have high specific heats. The biggest downsides are the various system components (pump, accumulator, gas separators, etc.) that may be required, and that the coolant must be thawed prior to reactor startup (or launched warm and kept warm). So, a thaw/heater system is needed to warm the coolant in the heat-exchanger, pump and core prior to operation.

Liquid metal cooled space reactors have been built and flown by the United States and the USSR, and are the most tested of all space reactor concepts. Most notable are the US SNAP reactor (Voss, 1984) and the Soviet BUK and TOPAZ reactors (El Genk, 2009). Another substantial US LM space reactor program was SP-100 (Truscello, 1992), but it did not result in a test or flight.

Other cooling options for a space reactor

Several other cooling methods have been postulated; some of them are briefly described below for completeness, but will not be included in the comparison.

A conduction only cooled core was investigated in the very early space reactor projects. It is a simple and elegant solution, but it is limited a few 100 W in power. Unless a super heat-conducting material can be found, the applications for this technology are limited.

Molten-salt cooled cores have been postulated as an alternative to pumped liquid metal. In general, a molten salt cooled reactor has many of the same positives and the same negatives as a liquid metal cooled reactor. But molten salt doesn't provide as good of heat transfer coefficients as liquid metal and this makes them slightly larger than a comparable liquid metal cooled system. A molten-salt reactor also may have unique chemistry concerns, although not necessarily better or worse than liquid metal. Being comparable to liquid metal, but slightly larger and heavier has meant that no substantial effort has been put into molten-salt cooled space reactors.

Water-cooled space reactors have been postulated, but the number of potential issues is large. The system would need to be at extremely high pressure at the temperatures needed for the reactor core. There are also chemistry issues that are manageable on Earth, but might be a major engineering problem for a space reactor. The large volumetric change with freeze/thaw is also a potential problem. Given these issues, no serious work has been done on water-cooled space reactors.

Another cooling technology that has been explored is a boiling-liquid-metal-cooled reactor. This concept has excellent heat transfer and therefore has a very good power-to-mass ratio. But the reactor dynamics is unpredictable without a large amount of nuclear test data. The impact of gravity on performance is substantial, and the testing of such a system is considered challenging because of the safety issues with boiling liquid metals. A boiling-liquid-metal cooled system has been examined analytically, but no real testing has ever been pursued.

A comparison of cooling technologies

The key to any comparative study is to provide a level, and well-defined “playing field.” This requires consistency in three main areas: (1) system requirements and attributes, (2) design approach and assumptions, (3) design methodology and tools. The best way to achieve a level playing field is for the same team of engineers to design the “competing” concepts in parallel, because this is the only way to ensure consistency in each of these three areas. It is also very difficult, and sometimes ill-advised, to try to compare reactor concepts with high-level comparisons. The best way to discriminate between concepts is to generate detailed designs and development plans for each concept. The value of the comparison depends on the level of thought and depth in the concept design and development plans.

In the discussion below, the disadvantages of the concepts are dwelled on more than the advantages. In cases where one concept has an advantage in a specific area and the other two have a disadvantage, an effort is made to avoid redundancy as much as practical. Things that are felt to be relatively equal obstacles for all concepts are not mentioned here (e.g., fuel fabrication, Be and/or BeO reflectors, etc.).

The order of listing is not necessarily in order of perceived magnitude of advantage or disadvantage, but because the reasoning flows better in many cases depending on the order of the listing.

Gas-cooled (GC) system Pros and Cons

The gas-cooled system considered here is a “direct-drive” concept—the core is in essence the heat exchanger that provides the delta-T (change in temperature) to the Brayton system. In general, the key advantages of this concept are its lack of an intermediate HX and other components, and relatively straightforward fabrication. The disadvantages are associated with the single-point failure loop which encompasses several unknown issues, and less ability to adapt core design (as opposed to an HX design) if Brayton performance is not exactly as expected while being developed.

Gas cooled advantages

Few components: The GC concept has few reactor components and subsystems. This can simplify design, procurement, and integration, and reduce technical risk. In addition, simple GC concepts could be constructed with relatively little need for technology development.

Fabrication: From a purely reactor standpoint, the GC reactor is probably the quickest to produce. This could be a significant advantage provided that the other components desired for testing (fuel, control, facilities, etc.) can also be developed/produced on the same time scale (i.e., there is less advantage to having the “reactor” ready early if other factors dictate the overall schedule).

Gas cooled disadvantages

System reliability: The entire flow system encompasses several single point failures that are dependent on the integrity of both the core and each of the Brayton components (leaks or blockages caused by launch loads, stress/creep, particulate release, mass transfer, erosion). Unfortunately, many of these issues might not occur until after several years of operation, and a nuclear-powered lifetime test that might flush out these issue may be prohibitively expensive. Brayton power conversion systems (PCS) are likely to be less reliable than the reactor, so most designs incorporate redundant power conversion systems. The problem with a GC concept is that a leak anywhere in any of the PCS can cause system failure. This system-wide single-point failure arises because the only practical GC concept appears to be one in which each PCS unit shares the same gas with the core; i.e., the use of an intermediate gas HX and/or redundant gas-flow through the core does not provide an acceptable specific power (power per unit mass of the entire system). The best option would be if reliable high-pressure, high-temperature, long-life, fast-acting, remote-control hermetic valves could be used to seal off a failed PCS unit, but that will be very difficult as well.

There is some logic for the GC reactor to have no Brayton redundancy, because if a certain percentage of Brayton failures are caused by leaks (or could subsequently cause leaks or significant particulate release), then the system may become less reliable when redundancy is added. There are also several additional pipes branches and welds associated with redundancy, all of which add to the potential list of single-point failures. Also, the GC system would require valves (in this case non-hermetic) to prevent flow through non-operating loops—these will decrease reliability if they fail to deploy when called upon or deploy inadvertently and close off a working unit (so redundancy could hurt in this regard too). The bottom line is that the GC reactor only makes sense if the user/designer is confident that a highly reliable Brayton PCS can be developed and used in space.

Sensitivity to Brayton development: The GC reactor concept offers little flexibility to change working fluid conditions (pressure, composition, temperatures) or relax reliability requirements as Brayton development proceeds. Integrated system performance can be surprisingly sensitive to component pressure drops. Problems with Brayton development could arise late in program relative to reactor development with little chance for the reactor to accommodate a change, whereas the other concepts would only require HX redesign or worst case could potentially utilize an alternate power conversion technology.

Impact of safety requirements: The simplest option for space reactor launch safety is referred to as intrinsic safety. An intrinsically safe reactor requires no specific safety mechanisms (e.g., safety rods) to remain subcritical if it becomes immersed in water. This sometimes requires that the core contains spectral-shift absorbers; i.e., materials that will absorb proportionally more neutrons in a flooded neutron energy spectrum as compared to the nominal neutron spectrum. Regardless, it is extremely hard to achieve intrinsic safety in a core with large internal coolant area (i.e., a void that can become flooded with water). The GC concept normally

requires the highest void fraction of the concepts considered, even if a high-pressure, high He-ratio coolant can be used. If intrinsic safety is not possible, it may be necessary to incorporate internal safety elements into the design, which is difficult because of the GC concept's pressure vessel, and may significantly impact reliability. This issue compounded by the GC concept's sensitivity to Brayton parameters, which could significantly change the required core coolant area as development progresses.

Decay power removal: The GC concept has several disadvantages when it comes to decay heat removal. It will be very difficult to pull heat from the core with a loss of flow. The path of heat from the internal core to the radial edge is impeded by the gas gaps (unless a monolithic core is used) and the core is generally of larger diameter and length than in the other options. It is also unlikely there would be enough buoyancy force on Moon/Mars to drive significant natural convection. The radiological safety consequences of core damage are lesser in space, but the loss of the reactor power might be life threatening to an astronaut (more so than radiation release). If a ground nuclear test is desired, then safety and approvals may be more difficult, and/or complicated by the need for additional emergency cooling capability.

Impact of fuel pin failure: Catastrophic failure of a single fuel pin, where portions of the fuel pin clad and fuel pellets are introduced into the gas-flow could be a mission ending event.

Leaks from a fuel pin have the potential to transport potential contaminants and radioactivity from the core to the power conversion system. In addition to introducing potential materials issues in the Brayton loops, pin failure could also introduce dose issues in the Brayton or nearby components.

Mass: The mass of a GC concept is usually significantly heavier than the LM and HP; unless Brayton's could be developed to use extremely higher pressure/lower molecular weight gas (HeXe is typically assumed) or perhaps super-critical CO₂. This mass disadvantage becomes even more significant for surface systems, because some form of 4pi shielding is generally required, and the GC reactor usually has the largest surface area to shield, very large pipes to route, and may require sliding reflectors (or internal control) for reactivity control as opposed to drums, which adds shield mass.

Gas cooled unknowns

Testability: Non-nuclear testing is made more difficult by the impact of electrical leads through the plenum (on flow distribution, potential leaks, and/or contamination of the working fluid in the test article). Also, heater/instrumentation failures or variation of test configurations will require breaching of the pressure boundary, which increases chance of contamination and/or schedule delays. Lack of inherent decay-power removal could require an additional safety system to be incorporated into a potential ground test (although for lower powers it may not be an issue). Overall, the testability of the GC concept appears relatively good, but it is possible one of the above issues, or an unknown will make testing more difficult than the other concepts. Also, the tightly integrated response of the core and Brayton system might require additional nuclear-powered dynamic testing.

Heat-pipe-cooled (HP) reactor Pros and Cons

The HP system considered here places Brayton heat exchangers directly adjacent to the reactor, and pipes route the Brayton gas past the shield. An alternative is to place the HXs one far side of the shield, where the HPs travel through the shield to an HP-to-gas HX (or to a potassium boiler to transfer heat if Stirling engines were to be used). The core is comprised of a monolithic block that contains the HPs and fuel pins, and allows good heat transfer in the case of failed HP(s). The key advantages of the HP system are in its reliability, testability, and flexibility in safety. The disadvantages are the potential impact of failed HPs and the complexity of fabrication and assembly.

HP advantages

Redundancy: The HP reactor has inherent core redundancy (the level of redundancy depends on the impact of failed HPs on performance). In addition, the HP reactor can be configured to provide excellent redundancy in the power conversion system (e.g., totally independent and redundant Brayton systems).

Design Flexibility: For a Brayton system, the HP reactor is far more flexible to Brayton system gas pressure and delta-T than the GC concept, which allows flexibility in the coupled reactor and Brayton system development. The HP reactor is also far more flexible than a GC reactor with respect to Stirling or TE power conversion (especially for surface reactor applications), but not quite as much as the LM system, which will be discussed later.

Uniform core temperature: A successfully operating heat pipe is essentially isothermal, whereas other concepts are colder at the coolant inlet and warmer at the coolant outlet. An axial temperature gradient can introduce thermal-structural issues. There are also some material concerns (e.g., loss of ductility with irradiation) that can be temperature dependent, such that the colder end of the core might experience a problem that would not occur if the core was isothermally warm.

Transient response and control: When heat pipes are operating within their limits, they act essentially as an infinite thermal conductors (relative to the other heat transfer mechanisms in the system). This simplifies the system response (and prediction/design of response) of the reactor power system to transient events. More importantly, there is no control action required to change the reactor power (i.e., no command to change flow rate through the core), because the reactor (if the physics are sufficiently simple) can load follow the power draw without any reactor control response.

Testability: The HP reactor can be designed with unobstructed access to the bottom of the core; thus, resistance heaters can be easily placed within fuel tubes to realistically simulate fission power deposition. This ease of testing can allow rapid build and test iterations during development, and thorough testing of the integrated flight-unit before launch. The HP reactor also allows

core instrumentation to be implemented without breaching a pressure vessel. This is not only a testing advantage, but also an advantage in monitoring startup and benchmarking initial operation in space. The HP reactor also offers the best decay power removal capability which could simplify ground test safety concerns. This may allow the ground testing of a more prototypic unit, by not requiring the integration of an additional heat removal system in the ground test article. The figure below shows the electrical testing configuration of the SAFE-30 reactor (Van Duyn et al., 2002) (Fig. 4).

Safety: The HP reactor has a very low core void fraction (even if all HPs are breached). This gives the HP reactor an advantage in mitigating water immersion scenarios. The HP reactor also provides the most flexibility if very stringent safety requirements are imposed, because the open access to the core bottom allows the use of removable neutron absorbers to further suppress reactivity in flooded conditions. The compact core geometry also allows the use of control drums, which could present a safety advantage. Finally, the HP reactor offers the best option for transporting the fuel separate from the remainder of the system (because the coolant loop need not be breached), which offers an option to simplify transport concerns.

Heat pipe disadvantages

Core fabrication and assembly: One of the biggest early design choices for a HP reactor is whether to use a modular or monolithic design. The modular design has several fabrication and assembly advantages, but a monolithic design provides a significant increase in reliability and performance—by providing good thermal bonding (heat transfer path) in the case of a failed HP. The Kilopower concept provides the simplest monolithic option (McClure et al., 2020), because the core monolith is actually the fuel. Higher power cores will require a structural monolith (perhaps stainless-steel), with fuel rods placed within it. The biggest issue with monolithic HP reactor fabrication and assembly is that several things have to go right in order to produce an acceptable end product. One possible sequence is to: (1) manufacture the core monolithic block, (2) bond heat pipe tubes to the monolith, (3) fill the HPs individually, (4) test the heat pipes with resistance-heating (integrally and individually) as much as possible with core instrumentation, (5) integrate the upper shield and HX assembly and attach (potentially braze) the HX onto the HPs, inspect and verify HX coupling, and (6) insert the fuel and weld on end-caps. There are other options that can be envisioned if problems arise in any of these steps, but no matter what option is chosen, great care will be needed for a successful product. The biggest risk is the cost and schedule risk of potentially running several “cores” through the procedure until a successful core is completed. The ability to fix errors may be the most important thing to focus on during development, in addition to a rigorous QA/QC plan. There are potential methods to drain, clean, and fill a HP if necessary, or perhaps un-braze and re-braze a HX, but it is unclear how well fabrication risks can be mitigated. If constructing a monolithic core is problematic, then there are also ways that the core could be made in segments and then bonded together in a final step. Or perhaps a modular approach could provide acceptable performance (perhaps with a liquid metal bond or fat braze). Fabrication and assembly issues are a function of the number of heat pipes, which appear manageable at powers $\ll 1$ MWt, and very difficult at powers $\gg 5$ MWt.

Potential for failed HP: A failed heat pipe is essentially a blocked flow channel for a typical reactor, but a failed heat pipe is probably more likely than a blocked flow channel in most reactors. HPs can be developed to have relatively low failure probabilities ($< 1\%$ appears easily achievable for most HPs using state-of-the-art technology), but given the large number in the core there is a good chance of one or more failing over a decade or more, so the system should be designed to tolerate failed HPs (depending on risk tolerance). If a HP fails, the power generated in fuel next to the failed HP must be transferred to adjacent HPs. This introduces four potential problems: (1) increased temperature and throughput of adjacent HPs, (2) increased temperature of the fuel pins near the failed HP, (3) increased temperature and thermal stresses in the monolith, and (4) increased stress in the heat exchanger. Each of these problems can have significant consequences, except perhaps the fuel pin temperature because the impact of isolated failed fuel

Fig. 4 Electrically-heated testing of SAFE-30 reactor coupled to Stirling convertor.

pins may not be too significant for the HP concept. The consequences of #3 and #4 can mostly be solved by designing a core with more, smaller components (which adds complexity), and/or more robust materials. All of these issues can be addressed via resistance-heated testing of a prototypic geometry.

Potential for HP failure propagation/cascade: Failed HPs increase the temperature and throughput of adjacent HPs, which in turn increases the failure probability of an adjacent HP (the increase in failure probability is mostly a function of design margin). This offers the potential for a failure cascade if there is not adequate design margin. The monolithic block design has the benefit of allowing heat to spread further away from the failed area, so that considerable heat can flow past the nearest adjacent pipes; regardless, design margins still must be well understood and tested to preclude the occurrence of a cascade. The key HP design margins are for power throughput (typically capillary and boiling limits) and corrosion. In most HP reactors the capillary limit is the closest margin, but HP failures may drive the adjacent HPs closer to the boiling or corrosion limits than the capillary limit.

HX/boiler thermal bonding: Brayton HXs will likely be slid over the heat pipes from the top, but enhanced thermal bonding may be needed to achieve high system efficiency (to minimize the delta-T from the heat pipes to the Brayton cycle working fluid). It may be difficult to promote and maintain adequate heat transfer. Candidate braze materials exist that should perform adequately, but this performance (including the effect of irradiation) will require demonstration. The braze will probably need retain about 10% contact with the HX sleeve/thimble and the HP wall to provide good thermal performance, and this contact must be distributed around most of the HP-HX surface area (e.g., it cannot be all located on the first few cm of the HP). The most significant stresses on the braze could occur because of a failed HP. A failed heat pipe will cool and axially shrink relative to the other HPs, and potentially fail the braze; although it may be of little consequence if the braze fails around a failed HP (in fact this may be good in reducing HX stress in a failed HP condition). If a braze becomes a significant issue, there are other options for thermal bonding, such as a gas or LM gap (which requires a hermetic vessel to be placed around the HP/HX assemblies, except for perhaps on Mars because of the atmosphere), thermal radiation (aided by high emissivity surfaces), or perhaps an integrated HP/HX assembly printed via additive manufacturing.

Heat pipe unknowns

Upper power limit: The manufacturing and assembly issues of the HP reactor make it difficult to project the upper power level at which a heat pipe reactor can be practical. Studies have indicated that a practical upper limit simple stainless-steel HP reactor might be $\sim 1\text{--}2$ MWe (Poston and Kapernick, 2012), but this is largely speculation. Advances in 3D printing might allow the fabrication of monolithic reactors with thousands of heat pipes, including integration with an HX, but there would still be other issues to resolve. If a modular, instead of monolithic core is selected, the power may not be limited by fabrication, but instead by diminished ability to prevent core overheat due to failed heat pipes. Second or 3rd generation heat pipe reactors could go to significantly higher powers ($\sim 5\text{--}10$ MWe?) if a refractory metal or carbon-based material (SiC?) could be used to increase operating temperature to $\gg 800$ K.

Pumped-liquid-metal (LM) Pros and Cons

The liquid metal system considered here is a fast-spectrum, pumped LM system. In general, the advantages of the liquid metal system are in performance (mass and flexibility), and the disadvantages are in development risk and reliability.

Liquid metal advantages

Scalability to very high power: The core power can be increased significantly in an LM reactor without a major increase in coolant flow channel area (depending on pump effectiveness, fuel performance, etc.). This can start to create a significant mass advantage at powers $\gg 1$ MWt, while at lower powers HP and LM concepts are often of similar mass, with GC concepts are generally heavier at all power levels.

Flexibility. Flowing liquid metal provides an excellent medium for transferring heat to most power conversion systems. The importance of this advantage depends on the development of future power conversion systems, and would be huge if low-mass, high-efficiency magnetohydrodynamic (MHD) energy conversion can be developed.

Liquid metal disadvantages

Freeze/thaw: Freeze/thaw is a complex issue that cannot be fully tested until a complete prototypic flow loop is completed. An adequate system for high-purity liquid-metal loading, freeze, thaw, and surface wetting must be developed and its performance verified. Specific issues associated with loading and freeze/thaw include the following: (1) High purity must be ensured. Flushing the system with high-purity fluid theoretically enables a high-purity final fill and provides the potential for maintaining high purity throughout the mission. However, the system must be designed to allow complete draining between certain operations, and all potential sources of contamination must be identified/eliminated. (2): The desired prelaunch location for the frozen coolant must be determined, the coolant must be loaded into that location, and the mass and location of the loaded coolant must be determined and verified to be within acceptable limits. (3): The system must be designed to keep stresses associated with initial coolant thaw within acceptable limits. Methods for measuring the stresses/strains associated with thaw must be devised and implemented for development and qualification testing. Methods for verifying that no unacceptable internal damage has occurred must also be devised/implemented. (4): Gravitational effects during development and qualification testing of the freeze/thaw system must be determined and compensated for. (5): The system should also be designed to accommodate anomalies in flight-system start-up, which could include partial melting/refreezing/re-melting of the coolant.

Testing difficulty: Realistic flow system tests are not possible until all components (core, pump, accumulator, etc.) are completed—delays in any one component could seriously set back a program. Test apparatus will be relatively complicated, and even when successfully completed, may have many glitches and be difficult to debug. It will be difficult to use resistance heaters to simulate realistic power deposition. The effort required to make any changes or corrections will be significant. When the coolant loop is breached to make repairs and adjustments, it will be time consuming and could introduce impurities. Each test requires unit to be unfrozen (and refrozen to desired inventory location).

Pump development and/or recapture: Liquid metal pumps have been successfully deployed for various applications. One of the potential pump technologies for space reactors is the Annular Linear Induction Pump (ALIP), an example of which is shown below. Unfortunately, the technology status of pumps for relatively low-power space application is in question—especially as a function of required performance (efficiency, reliability and mass). A decrease in pump efficiency (i.e., increase in required electrical power) propagates through the entire system with a substantial mass impact (plus the increase in thermal power increases “nuclear” issues, e.g., burnup, swelling, materials damage). The other issue of a pumped system is the additional complexity of providing and distributing power to the pumps (Fig. 5).

Reactor Instrumentation and Control: The additional components of the LM concept requires more diagnostics (both in number and unique technologies). This subsequently requires more collection and processing of signals, and more control commands to be given. The development and reliability of instrumentation and control will likely be more expensive and complex than for the other reactors, and require more integrated system testing.

Heat exchanger development and integration: The HX design and fabrication for the LM system has the potential to be simpler than for the HP system, however there are other problems with the HX specific to the LM design. The HX must be designed to allow wetting, draining, freezing, and thawing—the potentially small passages of the HX may introduce problems in this area. Also, in the case of the LM concepts each HX may represent a potential single-point failure.

Development risk (cost and schedule): There are a large number of technical unknowns with the LM concept mentioned individually below. These in combination with the difficulty of testing can cause significant increases in program cost and schedule, and more importantly it significantly decreases the probability of successful completion.

Liquid metal unknowns

Reliability and lifetime: While the single-point failure susceptibility may not be as great as for the GC concept (because of isolation from the Brayton loops and the difference in holding relatively low-pressure liquid-metal as compared to high-pressure gas), the complexity of the LM system makes it very vulnerable to reliability and lifetime issues. The difficulty, cost, and schedule of testing exacerbates reliability and lifetime issues to a potentially show-stopping level.

Gas-separator development: The need for a gas separator depends on the choice of coolant, and the magnitude/spectrum of the core neutron flux. Lithium and potassium generate gases via neutron absorption, while sodium does not. The operation of a gas-separator in zero-g that does not significantly impede flow is difficult, as well as hard to test in a gravity environment. The separator must also be designed to preclude the possibility the gas being reintroduced to the fluid due to a failure or off-nominal condition.

Coolant activation: This is another issue that depends on the coolant and flux magnitude/spectrum, but the bad actors are reversed when compared to the gas separator. Sodium (and thus NaK) can present a significant shielding/dose issue, while potassium and lithium are much less of a concern. Coolant activation is only a significant issue if the coolant is routed close to other radiation sensitive components, or if an astronaut needs to approach a shutdown reactor within a day or two (for repairs on the reactor or other infrastructure). The HP reactor mostly avoids this issue due to its low inventory, and all of this coolant is internal to the power system.

Integrated performance: There are enough coolant loop components (pump, thaw heaters, accumulator, and potentially gas-separator and/or chemistry modules), that even if components are successfully developed, it may be difficult to assemble them and operate them as planned as an integrated unit. The components must work together nominally, be able to tolerate off-normal performance in other components, and work together with the freeze-thaw strategy. The photo below shows technology demonstration unit for the NASA pumped-NaK fission surface power system (Briggs et al., 2016) (Fig. 6).

Fig. 5 Drawing and photo of a lithium Annular Linear Induction Pump (ALIP) (Adkins, 1984).

Fig. 6 Photo of NASA fission surface power technology demonstration unit.

Design constraints of each option

The design issues of each cooling technology are discussed below. Many of them overlap with the disadvantages discussed above, but are presented in the context of how they need to be considered by a reactor designer.

Gas cooled design issues

Reactor design flexibility: In the GC concept, Brayton development is constrained by core development and vice-versa, because both systems have to work with the same coolant flow rate, pressure drop, and delta-T. During the development process, if the Brayton system is found to be more sensitive to pressure drop than anticipated, the core design may not have enough margin to provide lower pressure drop, while it would be much easier to redesign an HX for an LM or HP system. Therefore a GC concept should be designed with extra thermal-hydraulic margin.

Reactivity control options: The GC concept can also be constrained in the selection of control options. External control can be difficult for a GC concept because it usually requires a larger diameter core (to provide the required flow and heat transfer area) and the potential need for thick cylindrical vessel, downcomer, baffle, and/or stagnant gap between the fuel and the reflector (depending on the design option). This may require a GC design to use sliding reflectors instead of drums, or perhaps internal control. Both of these options create development and performance difficulties, including problems with thermal management and shielding (Poston, 2021a,b,c).

Piping: The physical layout of gas piping can create integration and shielding issues. A single pipe to handle all of the gas flow can be many inches in diameter (depending on pressure and flow rate). This size of pipe introduces welding curvature issues at interfaces and cannot generally be packed into the system design without significantly increasing radiation streaming and/or shield mass.

Reactor temperature gradient: The thermal stresses of the internal axial temperature gradient must be accommodated. Also, the fuel pin is irradiated over the entire gas-coolant temperature range. Some materials issues, especially those involving radiation damage (loss of ductility), are significantly temperature dependent. This may not be an issue, but the higher the power/flux and the greater the temperature range of operation (delta-T), the greater chance that a negative materials issue could arise.

Launch loads: Launch loads will present issues for all concepts, but they may have the biggest impact on mission reliability on the GC concept (because of the large number of locations that contain potential single point failures). Launch loads, particularly random and lateral forces, will not be characterized until very late in the program, and even then, there will still be an uncertainty band and a random component to them. Launch loads on the core internals may be an issue, but the bigger issue might be the potential for a local stress at a pipe joint that damages a weak or even solid hermetic seal, creating a gas leak.

Erosion and flow induced vibration: The GC concept must consider flow-induced vibration of the fuel pins (unless flow through a monolithic-block reactor is used). Erosion could also be more problematic for the GC concept because of the complexity of flow paths and the need to flow the entire Brayton gas volume through the core (as opposed to being separated into lower-power HXs for the other Brayton concepts).

Transient response: Tight coupling and increased sensitivity to the Brayton operating state could result in dynamic issues (although it may also provide possible advantages). The lack of thermal inertia between the Brayton fluid and the fuel-pin could increase the chances of overheat scenarios (the LM concept has the Li loop, and the HP concept has the HX wall, the HP, and the monolith between the gas and the fuel). A GC concept might have more need for a nuclear-powered test to study and verify system dynamics.

Heat pipe design issues

HX/boiler fabrication: For a Brayton system, the HP-to-gas HX fabrication might require several welds and potentially difficult machining, although advances in 3D printing may eliminate this risk. There are many design options for the HX, but an annular flow geometry may provide the best combination of performance and fabricability. In an annular flow HX, the Brayton gas flows in an annulus along the length of the HPs, with inlet and outlet plenums on opposite ends. The figure below shows the SAFE-100 annular flow HX integrated with an electrically-heated HP reactor operating at 700 °C in a vacuum environment (Steeve, 2005) (Fig. 7).

A cross-flow heat exchanger offers some mechanical advantages, but will likely require more surface area, and may have more difficulty removing power from HPs that surround a failed HP. For a Stirling system, the potassium boiler should present no significant fabrication issues (except for the thermal bonding of the boiler to the HPs and Stirling engines as mentioned above). The key factor for the boiler will be thermal-hydraulic testing (including the effects of superheating), which will have to be correlated to the gravity environment of the Moon and/or Mars.

HX and shield integration: HX integration (the physical sliding of the shield and HX onto the HPs) is a design/fab issue for the HP concept. The design needs to allow for significant tolerances between the HPs and the HX holes, and the HP straightness tolerance must be tight as well. The tolerance of HP position in the x-y dimensions is not as crucial, because an “imprint” of the actual geometry could be taken and fed into the fabrication process if x-y tolerance was found to be an issue. The difficulty of integration depends on the number of HPs and HXs, and could become very difficult for high power (> 1 MWt) cores with several Brayton loops. Physical integration was not found to be a problem with the SAFE-100 test article shown above, but this HX only incorporates 19 HPs.

Operating temperature flexibility: The HP reactor has several factors that must be balanced to determine the optimal core operating temperature (i.e., the heat pipe temperature). All reactors need to balance the desire for high temperature to the PCS while maintaining sufficiently low temperature to the core materials. The heat pipe reactor has an additional constraint, in that the heat pipes must be warm enough to have sufficient power throughput limits. Also, the in-core x-y temperature gradients caused by failed heat pipes are usually greater than the delta-T in the other concepts. In most cases, at low powers $\ll 1$ MWt, there is sufficient margin to accommodate all issues. At higher powers, the larger core temperature gradient, more delta-T between the heat pipes and PCS, and higher heat pipe throughput requirements can make the window tight to accommodate. This in conjunction with the fabrication issues discussed earlier probably make the HP concept unattractive at powers $\gg 5$ MWt (until perhaps refractory heat pipe reactors could be developed).

Fig. 7 Electrically-heated testing of the SAFE-100 reactor coupled to annular flow gas HX.

Liquid metal design issues

Redundancy impact: The level of PCS redundancy required for an LM system can impact design significantly, and have a surprisingly negatively impact on mass. Consider the use of four 50%-power independent PCS units. (1) If the HX are in series (and you assume two are working and the other two have failed or are in standby), the furthest downstream working HX will have coolant at a temperature lower (by about half the core delta-T) than the upstream HX. Ideally, you would design the downstream HX to be larger (to achieve the same PCS temperature), but the middle HXs may have to operate as either upstream or downstream (depending on which other HX/PCS is working), so there is no way to tailor their design. This leads to two issues, (a) all HX need to be designed to the worst case (lowest liquid-metal temperature—thus highest mass, highest gas delta-P) condition, and (b) the gas temperature and/or thermal power will be different in each working PCS loop, so the PCSs will operate at different state points. (2) If the HX are in parallel, “bypass” flow in the non-working HXs creates a significant problem. If 2 PCS loops are being used as part of a 4–50% PCS system (and LM flow continues through all), the delta-T in the working HXs will have to be ~2-times the core delta-T; this lowers the exit temperature of the working fluid from the HX, and thus lowers efficiency. Also, the size, mass, pressure drop of the HX has to be designed to meet this colder LM temperature condition, which will be much larger than for a HX designed for the nominal case. Therefore, if a parallel configuration is used, it is likely that valves will be incorporated to close-off non-working HX/PCS branches. This also requires additional hardware and development to instrument and control the valves, and more importantly the system will rely on the reliability of those valves. In both cases (series and parallel) the closer the coolant temperature is to the desired hot PCS temperature, and the higher the core delta-T, the worse this issue gets. This issue is unique to the LM concept because the HP concept has a very small delta-T along the heat pipe, while the GC concept would never use redundant systems in series, and the parallel issue was already discussed with respect to reliability.

Core support and flow configuration: The fuel pin/core support structure must be designed to prevent flow-induced vibration and/or clumping depending on flow direction. Most LM concepts use either a 1-pass or 2-pass flow configuration. A 2-pass flow configuration has down-flow in one section of the core and up-flow in the other. This allows a compact reactor design, but significantly increases core pressure drop (thus pump mass/power) due to the decreased flow-area of each pass, and could also create internal core thermal stresses. Many designs use a downcomer (an annular region surrounding the core) to feed coolant to the inlet of a 1-pass core. The generally reduces pressure drop, but adds reactor mass because it separates the fuel from the radial neutron reflector. Other designs will use feed pipes outside of the pressure vessel to feed coolant to the inlet of the core; this mitigates the mass penalty of a downcomer, but complicates system integration and creates additional regions where stresses and potentially leaks could occur.

Control system “knobs”: The LM system has an additional knob to use in reactor control (i.e., pump power/flow rate) than the other systems. This adds complexity to the instrumentation and control system, and can create scenarios where the flow control system conflicts with the PCS control system; i.e., where a change on one control variable causes a change in the other, such that both systems have to actively respond to each other. This effect complicates control algorithms significantly, and introduces additional reliability concerns. Note that there may be some operating scenarios where the flexibility provided by an extra control knob could be beneficial, but for a system that has to operate remotely and reliably for years simplicity is probably preferred.

Pumping power requirements: The need to provide electrical power to the pump introduces several issues (unless the pump is powered internally by its own thermoelectrics, which is a separate development issue). This power system development becomes very sensitive to the pump development, most importantly in terms of pump efficiency (if the pump doesn’t meet the desired efficiency the entire system can quickly become unattractive). In comparison, the GC concept will generally have a much higher thermal pumping power, but this is effectively/efficiently incorporated into the Brayton turbomachinery, while the HP concept uses passive physics to “pump” the working fluid. The LM need for pumping power also requires the PCS to create more electrical power than the other systems. This not only makes the PCS and heat rejection system larger, it also requires a higher power reactor. A higher power reactor can exacerbate “nuclear” issues (burnup, swelling, materials damage) depending on the design, and increases the shield mass (which may also be required to cover more radiator space). There is also the additional complexity of distributing and controlling power to the pump(s).

Conclusions

There are three classes of reactor that appear to be best suited for near-term space reactor applications: gas-cooled (GC), heat-pipe-cooled (HP), and pumped-liquid-metal-cooled (LM). It is not possible to make a blanket statement regarding the superiority or inferiority of these options, unless very specific performance criteria are provided: e.g., power, lifetime, environment, mass, reliability, etc. However, some generalities generally hold true. GC concepts are only well-suited for relatively high-power space applications ($\gg 100$ kWe) and are only practical with Brayton power conversion (in particular, high-reliability Brayton systems). HP concepts are the most attractive option at lower powers (< 100 kWe) and in cases where high system reliability is emphasized. LM concepts are often the most attractive when low mass is desired at relatively high power levels ($\gg 100$ kWe). Unfortunately, the number of caveats to the above generalities, and the ultimate details of every mission application, make it unwise to make design decisions based on the above.

In some ways it is unwise to speculate on what future high-power, high-performance space reactors might look like. A lot will depend on how each technology progresses in the future. GC concepts would gain an advantage with progress in space Brayton technology, and if methods to prevent and potentially repair gas leaks were developed. HP concepts will gain an advantage if

progress in 3D printing continues, and if another HP reactor concept like KRUSTY (McClure et al., 2020) is developed and tested. LM would gain an advantage if progress is made in LM pumps and a new LM reactor is successfully deployed on Earth.

Most important may be how “reactor” technology progresses; i.e., the design, built, and operation of actual reactors, instead of progress on specific reactor technologies. Reactor technology can be considered as the knowledge and infrastructure to create actual working reactors, which is somewhat independent of the specific reactor components. This is the “technology” that is most severely lacking in the present day (2020). The best way to advance reactor technology is to start with simple and affordable systems that have a decent shot (>50%?) of being actually being successfully developed, as opposed to the numerous failed space reactor programs of the past, which have pursued high-performance reactor programs with low-probability of success (Voss, 2021). For this reason the simpler, low-power HP reactor concept may be the best place to start, especially since these low-power HP concepts can provide near-term benefits for surface power on the Moon/Mars and for science missions (Poston, 2021a,b). These early generation HP power systems could then evolve to even more enabling high-power HP, GC and/or LM systems.

Acronyms

ALARA	As low as reasonably achievable
B ₄ C	Boron carbide
DPA	Displacements per atom
EHA	Extra-habitat activities
GCR	Galactic cosmic radiation
LiH	Lithium hydride
NaK	Sodium potassium eutectic
NEP	Nuclear electric propulsion
NVT	Neutron velocity time
PMAD	Power management and distribution
SEU	Single event upset
SFP	Space fission power

Introduction

The primary function of reactor shielding is to prevent the transport of reactor neutrons and gammas to sensitive locations. For space reactors, radiation shielding is an integral system design concern, as opposed to most terrestrial reactors, where shielding can to some extent be left as an afterthought. This is because mass, volume, and separation are all valuable commodities in space, while they are rather easy to obtain on Earth (except for submarines in some respects). Space reactors also don't have the benefit of regular maintenance to replace components that might be sensitive to radiation. The difficulty of cooling

or thermal management in space also can make shield design difficult. The combination of these and several other system issues (launch loads, differential expansion, radiation tolerance, etc.) requires that shield design be an integral part of the space reactor design process.

First order, the biggest complication of shielding is mass; i.e., if mass were not an issue, shielding would not too difficult. It is the desire for low mass that leads to the selection of materials and geometries that make engineering difficult; although this is often a necessary complication, or shield mass could end up dominating the entire power system mass.

Radiation shielding criteria and requirements

Radiation shielding should never be considered a fixed high-level mission requirement. Shielding requirements should be considered and constructed as a means to best complete a mission: this starts with determining what the goals of a mission are. Shielding considerations might help decide whether a certain type of measurement or capability is practical, whether a function is performed by one instrument or another, how long a mission should last, where human activities could take place, etc.—all of these factors must be weighed against shield mass and complexity. Even once mission requirements are set, there will be many trade-offs that determine how much physical shielding is needed; e.g., how hard should one try to find or develop rad-hard (radiation hardened) components, how much separation or boom length (separating reactor from payload) can be utilized, how much redundancy should be considered for radiation sensitive components, are there in-situ materials at our destination that could help with shielding, etc. In an ideal engineering world, every space fission power (SFP) mission/system would be designed and developed in this manner. In a practical engineering world, a successful space reactor will probably need to be flexible enough to provide shielding for many applications, such that shielding modules and/or features could be added or removed depending on the mission (as long as this does not complicate system structural, thermal, and neutronic performance).

As discussed above, “radiation shielding requirements” should be part of the evolution of requirements from mission, to system, to function, to component. The only true requirements are component radiation requirements, which might ultimately be translated to regional radiation requirements once a configuration is fixed. Note that a “component” can be a transistor, a magnet, an epoxy, a telescope, a fuel tank, or even a human being. Each component will have its own radiation limits or requirements, in fact the shield itself will often have its own internal radiation requirements. Once a mission shielding solution is determined, the only true requirement for reactor shielding might be how much the fluxes/doses need to be reduced; often measured in orders of magnitude or decades.

In general, there are two sources of reactor radiation that need to be shielded: neutrons and gammas. The neutrons of concern are almost entirely from fission (prompt and delayed), with a small potential number from $(n,2n)$ reactions and an occasional photoneutron. Gammas of concern are from fission, radioactive decay products, and neutron capture, in every region of the reactor (core, reflector, vessel, and the shield itself). In this encyclopedia the terms photon and gamma are used interchangeably, because lower energy photons do not generally travel far enough though their source material, nor carry enough energy to be of significant shielding concern (although in some cases hard X-rays, between 5 and 50 keV, can make a noticeable contribution). The highest gamma energy of significant quantity from a reactor is ~ 20 MeV, which is a long way from the highest class of photon, referred to as very high energy (VHE) gammas (> 100 GeV). Charged particles, notably beta, alpha, and fission products do not escape from the reactor at a high enough rate to present a shielding concern; although most of the actual damage from high energy photons is caused by the electrons it dislodges (thus the term ionizing radiation). Neutrons are not directly ionizing, but significant ionization does result from most neutron interactions. For a space reactor, high energy charged particles and VHEs can be of concern due to galactic cosmic radiation (GCR), solar flares, and within the radiation in the belts of Earth, Jupiter, etc. For missions in a high background radiation environment, e.g., Jupiter, the shielding solution must balance reactor and background effects.

The negative effects of neutron and gamma radiation are usually binned into two categories: cumulative damage effects and single event effects (SEEs). As the name implies, cumulative effects depend on how much radiation dose a component receives over time. The performance of the component (processor, memory, insulator, etc.) might degrade gradually with time until it is partially- or non-functional. Single effects are generally caused by the direct interaction of a single high energy particle with a component, where the resulting flood of electrons causes a failure. A common SEE is a single event upset (SEU), in which a change of state (e.g., flipping of a bit) occurs in a component. Damage from an SEU is usually not permanent to the component, but the temporary failure of the component could cause a system to fail (e.g., cause a faulty result, lock up a computer, etc.). The net effect of an SEU usually depends on the robustness and/or redundancy of an architecture, and the importance of the specific electronic feature that is affected. Other SEEs can have destructive effects, like single event burnout (SEB), single event latchup (SEL), etc. Since a SEE is a random 1-time event, the probability is linear with the radiation flux or dose rate. All of the damage phenomena tend to increase significantly with particle incident energy, and some phenomena have threshold values below which radiation will not cause a problem. Over the years, SEEs have become an increasingly significant issue as the feature size of electronics have gotten smaller, progressing from the mm range to the nm range. As the size gets smaller, the critical charge (i.e., number of electrons/ions that can cause a fault) continues to decrease.

Neutron dose limits: The cumulative damage from neutrons depends on many factors. In most materials, the most significant damage is displacement damage, in which a neutron knocks an atom of its nominal lattice position. This can change the electrical

properties of a semiconductor, the strength and ductility of a metal, the swelling of a ceramic, the magnetic properties of a magnet, etc. The potential for damage is usually defined as a function of displacements-per-atom (dpa). For most materials, dpa is a function of neutron fluence (cumulative number of neutrons crossing a unit area); in general, most dose limits are expressed as a function of neutron fluence. The displacement damage potential is a strong function of neutron energy, and in many cases the damage is expressed as a function of “1 MeV equivalent neutrons” or “> 100 keV neutrons.” Since fluence is equal to flux accumulation over time (n/cm^2), and flux equals number density, n , times velocity, v , then fluence is sometimes referred as neutron-density velocity time (nvt). In most cases when nvt is used with respect to irradiation damage, it implies fast fluence, such that nvt implies the fluence of 1 MeV equivalent neutrons.

The damage tolerance of components range from $1e10$ nvt (bipolar silicon electronic components) to $> 1e23$ nvt (structural steels). Most off-the-shelf computers might tolerate between $1e10$ and $1e11$ nvt, but standard rad hard components should allow space reactor computers up to $\sim 1e12$ nvt without excessive cost, mass or power budgets. Tolerance up to $1e13$ nvt should be possible, but may be expensive, heavy, and/or power intensive. Another concern is the damage neutron fluence can have on reactor components like bearings, magnets, epoxies, coatings, etc. Magnetic integrity is of great importance for most space reactors because of the motors that move control elements and the alternators that produce electricity. Commonly used magnets might incur significant loss of performance (remanence) at fluences in the range of $1e14$ – $1e15$ nvt. Bearings for the control elements might be effected, either by changes in surface roughness and/or greases/oils (if used). Organic components, perhaps resins or epoxies, can also be intolerant to neutron radiation. Note that all the numbers listed above are general estimates, and can depend significantly on temperature or the details of the neutron spectrum.

The ionizing effect of neutron collisions also provides some damage, but generally on a smaller scale than gammas, because only a fraction of the neutron energy might lead to ionization, while nearly 100% of the gamma energy is ionizing. The other significant source of neutron irradiation damage potential is caused by neutron induced transmutations (the change of one isotope into another, or into a pair of products). The most common issue is the production of a gas after a neutron absorption, and this gas can lead to swelling, loss of ductility, cracking, etc. Many potential space reactor materials have the potential to create gases: Li, Be, B, C, Ni. Gas production is sometimes a serious issue within the shield itself, either $^3H + He$ from 6Li or He from ^{10}B . Neutrons can also dissociate the H from LiH, which is a flux issue rather than a fluence issue. In the case of LiH, potential radiation issues sometimes lead to the requirement to “shield the shield,” i.e., place a more robust shielding material, like Be, on the leading edge of the LiH to reduce its dose. Nickel-containing alloys are known to undergo helium embrittlement under very high fluences, but that is an in-core issue, not a shielding-related issue.

All of the above discussion is meant to give a flavor of the type of issues that might require neutron shielding. Any space reactor system design will require a detailed evaluation on a component-by-component basis to determine the appropriate radiation limits. In many cases this will require in-pile irradiation testing. Unfortunately there is very little neutron irradiation data for non-nuclear materials, especially for space rated electronics. This is because the space environment has very few neutrons, so relatively few customers or vendors have taken time to evaluate neutron tolerance (as compared to photons and charged particles).

Gamma dose limits: The cumulative dose damage from gammas is much easier to characterize than for neutrons; except for VHE gammas, which as mentioned previously are not a reactor shielding concern. The ionizing damage from gammas, and X-rays, is essentially proportional to the total energy deposited by a photon. Damage thresholds for most materials and components are expressed as a function of Rad ($1e-5$ J/g), or sometimes Gray (J/kg). Every material is different in how it interacts with photons. Energy deposition from radiation to matter is defined by Kerma (kinetic energy released per unit mass); every material has a different set of Kerma conversion factors. The difference in Kerma among materials is not very large for fission gammas (averaging few MeV), but can vary significantly at other energies depending on atomic number (i.e., number of electrons per atom). Most often dose limits are expressed in Rad(Si), because Si is the most common material of interest; even components with little or no Si might have their dose limits expressed as Rad(Si) by convention.

The bulk of gamma dose is ionizing dose, which causes gradual degradation of material performance. The damage threshold for even the most sensitive parts is generally ~ 10 kRad, thus accumulated gamma doses < 10 kRad are not usually of concern. Sensitive, non-rad-hard electronics might start to lose functionality at a dose of ~ 25 kRad, although there is a chance that limit could drop even further as the feature size of modern electronics continues to drop. However, there are many COTS (commercially off-the-shelf) electronics available that allow > 100 kRad, and up to 1 MRad. The figure below displays the total ionizing dose threshold (i.e., where damage can begin to occur) for various components. More information and the descriptions of components can be found in the reference from which the figure was obtained ([Messenger and Ash, 1992](#)).

In general, the use of rad hard components will save shield mass, but add cost, diminish capability, require more power, and/or require more cooling. The “good news” about component gamma/ionizing dose is that the limits are much easier to quantify than for neutron dose, both because of existing data, and the relative ease of obtaining new data via a gamma source, versus a neutron source or reactor.

Dose rate limits

The neutron and gamma dose limits discussed above are cumulative, and effectively independent of dose rate. There are other cases where damage or failures are a function of dose rate: this is true both for electronics and human beings. One way that dose rate can impact component degradation/failure is if the materials have a self-repair or annealing mechanism. For example, some metals will anneal out displacement damage at a sufficiently high temperature. If the rate of self-repair (often a function of temperature) is similar to the rate of damage caused by a specific dose, then the component can survive to a higher total dose, and perhaps indefinitely with respect to that specific dose.

The most significant impact of dose rate might be the effect of SEEs on electronic components and functionality. Some SEEs can cause permanent physical damage, but others cause temporary disruptions which may or may not cause a system failure depending on the rate. SEUs are stochastic and generally a linear function of flux or dose rate. As such, the same number of total SEUs might be expected for a flux of $1\text{e}3 \text{ n cm}^{-2} \text{ s}^{-1}$ for 1000 s as compared to $1\text{e}6 \text{ n cm}^{-2} \text{ s}^{-1}$ for 1 s; the difference between these two scenarios might be how the logic circuitry handles upsets. Most circuits have some ability to tolerate individual bit failures, using error detection and correction logic. The problem with high dose rate is that several bit failures might occur over a short period of time, which could overwhelm the components/circuitry and cause a system failure. This failure might cause a shutdown and reboot, or could permanently lock the system.

Human dose limits

The effects of radiation on humans is discussed in other chapters in this encyclopedia (Dewji and Miller, 2021; Kocher, 2021). There are two primary health risks to humans from radiation.

Radiation sickness: this occurs after a very high dose ($> 100 \text{ Rem}$) over a short period of time. Fatality is associated with dose $> 500 \text{ Rem}$ over short period of time. This can only occur if someone was standing close to an insufficiently shielded reactor during powered operation.

Latent cancer: this is harder to quantify and is rather controversial. Most US policies recognize the highly conservative Linear-No-Threshold (LNT) model, which assumes that any dose (no matter how small) incrementally increases one's chance of later developing cancer. This risk is considered a cumulative effect, and is not a function of dose rate.

There are other potential risks including eye damage, reproductive issues, etc., but the two above generally define human dose limits, and the latter risks are used on a case-by-case basis if they are pertinent.

In the nuclear industry, the ALARA principle (As Low As Reasonably Achievable) is generally the human dose standard. A limit of 5 Rem/year for a nuclear worker was established as a reasonable balance between productivity and risk, although there is no significant evidence that 5 Rem/year provides any risk at all. In space, a 5 Rem/year limit would preclude stays on the space station, so NASA has used ALARA to balance productivity and risk with a much higher dose guideline of 50 Rem/year. NASA career limits are based on age and sex, from 100 Rem for a 25 year-old female to 400 Rem for a 55 year-old male. These dose limits are based upon a maximum 3% lifetime excess risk of cancer mortality, which is a relatively small risk compared to the numerous risks faced by an astronaut, especially on a potential Mars mission. The total natural dose from a Mars mission is expected to be ~120–150 Rem over 3 years, which is acceptable, but even if a mission scenario exceeds the current NASA limits, the dose allowance could be increased based on a benefit/risk basis.

If a reactor is used on a human mission, whether for propulsion or power, the dose from that reactor should be weighed against the improvements it provides to mission capability. In some cases a reactor can also provide enhanced safety; e.g., if a Mars surface reactor provides more reliable life-support than a solar array (perhaps due to dust storm concerns), or a nuclear electric propulsion (NEP) system helps reduce travel time.

The reactor radiation dose limit should depend on benefit/risk, but at a minimum the reactor limit should be 5 Rem/year if it significantly enhances the mission. 5 Rem/year is the level accepted for personnel on Earth, and more-so has been proven to be safe (health statistics of nuclear workers receiving 5 Rem/year or less have not shown any negative effects). If the reactor is truly enabling or provides increased astronaut safety, then an acceptable additional dose from the reactor might be 10s of Rem/year.

There are two primary points:

- 1) There are no hard dose thresholds or limits that should apply across the board for all astronaut missions. NASA currently has a 50 Rem/year guideline, but going higher or lower will not significantly change the integrated mission risk for an astronaut that leaves Earth orbit (because numerous morbid mission risks will likely far exceed the additional risk of developing cancer later in life).
- 2) Radiation dose should not be considered a zero-sum game. If a reactor provides a dose of 5 or 10 Rem/year, the decision to use the reactor should be independent of the expected natural radiation dose for the mission. The increase in radiation risk caused by the reactor is the same regardless, i.e., if the reactor provides 5 Rem/year, there is no difference in added risk going from 10 to 15 Rem/year or from 50 to 55 Rem/year. The decision to use the reactor should be on its own merits, i.e., does the risk from the reactor radiation outweigh the benefits and increased capabilities provided by the reactor.

Shielding material options

Any material can generally be used to shield neutron and gamma radiation, but the selection of space reactor shielding is limited by several factors: including the desire for low mass, the difficulty of thermal management, the lack of gravity, the ability to survive launch/landing loads, etc.

Neutron shield materials

The primary function of neutron shielding is to scatter neutrons. The scatter of a neutron is a win-win from a shielding perspective. The change of direction caused by a scatter will usually decrease the probability of the neutron reaching the shielded area. The slowing down (decrease in energy) caused by a scatter will almost always reduce the damage caused by the neutron if it reaches the shielded area. Ironically, the ultimate absorption of the neutron is not a neutron shielding issue, but rather a gamma shielding issue, if the capture results in one or more gammas.

Most elements/isotopes are similar in terms of how they interact with fast neutrons, with heavier elements having a slightly higher interaction probability (cross section); however, the best neutron shields are low atomic mass elements because they are more effective at scattering neutrons per unit mass, plus they slow down (decrease energy of) neutrons more per scatter. The latter effect generally makes hydrogen the preferred element for neutron scatter, if a hydrogenous material can handle the physical, thermal, and irradiation requirements of the intended application.

Lithium hydride

Lithium hydride is often the optimal space reactor shield, because it is a very low mass-density hydrogenous material. ${}^6\text{Li}$ is also a strong neutron absorber, which is desirable in a hydrogenous material to reduce capture gammas. Hydrogen neutron capture produces a 2.2 MeV gamma, which then creates a shielding issue in itself. ${}^6\text{Li}$ produces minimal capture gammas, and it preferentially captures neutrons over hydrogen. Naturally enriched Li contains 7.5% ${}^6\text{Li}$, and the fraction of captures within the Li will

depend on the neutron energy spectrum. The fraction can be increased by raising the ${}^6\text{Li}$ enrichment level; this not only reduces H capture gammas but also decreases mass because ${}^6\text{Li}$ is 6/7 the mass of ${}^7\text{Li}$ (which represents a significant shield mass savings).

Unfortunately there are several engineering issues associated with the use of LiH. The first complication results from the benefit described above; i.e., instead of producing capture gammas, ${}^6\text{Li}$ produces He and tritium gas when it captures a neutron. This causes the LiH to swell under irradiation, with significant swelling occurring at an ionizing dose of ~ 500 Mrad (Wang et al., 2016). However, swelling does not occur if the temperature is high enough to allow the gases to diffuse out of the material. Testing indicates that significant irradiation swelling does not occur at $> \sim 600$ K, although this will be dependent on can internal pressure and how the LiH is manufactured.

The other significant issue involved with LiH is potential H loss. Hydrogen dissociation pressure is very low at ~ 600 K, but is rather high above 800 K. In addition, H moves through SS and potential coatings much easier as temperature increases. Therefore, hydrogen loss from LiH generally starts to become significant at 800 K, becomes problematic about 900 K, and likely a showstopper at 1000 K; although with coatings or thick walls the loss rate might be mitigated with a properly engineered clad/containment.

In low dose regions ($< \sim 500$ Mrad), LiH can be used at low temperature without much concern. At high doses, LiH should only be used if its temperature can be maintained between ~ 600 K and ~ 800 K. This is a very difficult engineering challenge, especially because LiH has poor thermal conductivity (and potential for cracks). Power deposition is sharply higher in the regions near the core, and the inability to spread and reject the heat can be problematic. If LiH is used in a high dose region (resulting in high internal power deposition) then a design may need conductive plates, rods, wires mesh, etc. interspersed with the LiH to help remove heat. Another factor that complicates design is that LiH has a thermal expansion coefficient twice that of SS, which is the most likely can material. Also, there is relatively little experience and infrastructure for manufacturing LiH. Despite all of these challenges, the mass benefit of LiH is substantial enough to warrant its selection in many cases.

Boron carbide

Boron carbide (B_4C) is a well-established nuclear material; it has been utilized extensively as a neutron absorber (for control and shielding) in almost every reactor ever operated. The biggest advantages of B_4C are that (1) it is a high temperature material, (2) material performance is well characterized in extreme temperature and fluence regimes, and (3) there is an existing infrastructure to process and fabricate B_4C , either as solid components or as a powder. Boron, specifically ${}^{10}\text{B}$ is a nice neutron shielding material because it emits a rather low energy gamma (478 keV) when it absorbs a neutron, as compared to the 2.2 MeV hydrogen capture gamma. The other nice attribute of ${}^{10}\text{B}$ is that it is 9% lighter than ${}^{11}\text{B}$, so highly enriched boron is preferable, unless cost or availability dictates otherwise.

While B_4C does not have the upper temperature limit of LiH, it does have the potential to swell due to He production associated with ${}^{10}\text{B}$ neutron capture. One option to reduce swelling is to use low theoretical density B_4C parts. Another option is to use a fine powder, such that most of the He could escape the material and thus not cause swelling. A shield where B_4C powder is placed in a can (perhaps made of SS) is probably the easiest and lower cost option to fabricate. State-of-the-art techniques might allow packing fractions from 75% to 85%. The biggest drawback of a powder shield is very low thermal conductivity. The concern is not that the B_4C itself will get too hot, nor the SS can (except for extreme examples); the issue may be the difficulty of transporting power through the B_4C shield. Some reactor concepts require power to escape through the shield for thermal balance or decay heat removal reasons. Another risk of a powder shield is the potential for the material to sinter and then create localized stresses in the can during thermal cycles.

The primary drawback of B_4C is that it results in a significantly heavier neutron shield than LiH. The overall mass penalty of using B_4C largely depends on how it helps reduce gamma shield mass; B_4C not only shields gammas better than LiH, but also produces much lower energy capture gammas. However, in most cases this gamma shielding benefit does not come close to offsetting the mass penalty of B_4C as a neutron shield. A B_4C shield is generally only desirable if the potential for high temperature or high dose makes the use of LiH too high risk (the risk of losing hydrogen from the material), or the system design can benefit from the better structural properties of B_4C . In some cases, B_4C is best used as a leading-edge shield to reduce dose and power deposition to acceptable levels for a subsequent layer of hydrogenous material. It is unlikely that the lower cost or shorter procurement time of B_4C would be a major advantage for a flight reactor program.

Water

Water is potentially an attractive neutron shield material for surface power missions, especially if in-situ water can be used in future architectures. Water is not a good shielding option for zero-gravity (zero-g) space missions because the absence of gravity creates uncertainty and variability as to where voids may exist, plus there's no driving force (buoyancy) to convect heat within the shield (the thermal conductivity of water is very poor). It might be possible to use surface tension and capillary forces to mitigate these issues, but the benefits of water shielding would likely not justify the complications for shielding in zero-g.

Water is very effective at shielding neutrons, similar to LiH. The major advantages of using water shielding are design simplicity and cost. Prototyping and testing can proceed immediately and at low cost, which translates to rapid, inexpensive development, and low-cost flight units. There is a wealth of fabrication and operating experience with SS or Ti and water, and a significant irradiation database. A water shield is also very easy to test. Radiation transport can be tested with portable sources or in research reactors, although the nuclear cross sections of water are very well understood and in a gravity field there is no opportunity for streaming paths (dependent on the design). Thermal-structural performance can be tested inexpensively with electric heating to verify heat transfer, natural convection, and structural integrity (although the difference in gravity has to be accounted for). Also, the ease

of testing allows several potential configurations to be tested, which can be used to better optimize the shield and power system design. One other advantage of a water shield is the potential to use borated water to cut down hydrogen capture gammas, which can provide a modest reduction in shield mass if there are no significant chemistry or pressure issues. The shielding effect of ^{10}B in a water shield is investigated in Poston.

One of the limiting issues in using a water shield is temperature. The vapor pressure of water rises dramatically as it heats up to $\sim 400\text{ K}$, and at temperatures $> 450\text{ K}$ the thickness of the pressure vessel could make the shield mass excessive. In space, the low thermal conductivity of water would make it very difficult to keep the temperature low, even with small power deposition and/or throughput. In a gravitational environment, natural convection should be able to keep the ΔT through the shield reasonably small, depending on shield geometry and where the heat is added and rejected. Natural convection could also provide a significant system-wide thermal management benefit in configurations that require heat removal from the core/reflector assembly.

Another concern with a water shield is the impact of radiolysis (radiation induced breakdown that can lead to corrosion). Water chemistry is a major issue in all terrestrial water-cooled reactors. A water shield would probably not make sense for a space/surface system if an active chemistry system were required. Fortunately, the expected temperature and irradiation of a surface reactor water shield should be lower than the coolant in most terrestrial reactors. Titanium might be preferred as the shield vessel/can, because it is less chemically active with water (and radiolytic components) than SS. Freezing of the shield may also be a concern, but it is possible that water in a mostly wide-open vessel will tolerate freeze-thaw without any special attention (depending on how many penetrations there are through the shield, the overall geometry, the space available for expansion, and the number of thermal cycles). If freeze-thaw is found to be a design issue, it may not be too difficult to keep the water from freezing, especially after initial operation if there is some decay power being transferred to the shield. Expansion volume will also have to be available for the heated water. Depending on the peak design-basis temperature, it could be that the expansion volume required for freezing is the same as the expansion volume required for heating. Another issue with a water shield is the potential for leaks. If it is determined that a leak is a significant mission reliability issue, then different approaches (e.g., double wall or multi-compartment) would need to be investigated. There is a good chance that water will be used for system heat rejection and/or elsewhere in the system architecture, so the technical issues associated with water will need to be addressed regardless of the shield material.

Beryllium

The high scattering effectiveness and low density of Be make it a decent neutron shield, although not nearly as effective as LiH or water, and generally not as effective as B_4C . However, Be has a niche for space reactor shielding, particularly as the “leading edge” of a high power reactor shield. The high temperature capability and thermal conductivity of Be allow it to tolerate and transport power deposited in a very high flux/dose regions. The high strength of Be can also allow it to serve as the structural foundation for the entire shield. A small additional benefit is that the Be will reflect more neutrons back to the core and therefore increase nominal reactivity; although this might be a disadvantage for a particular modular shield, because it might cause reactivity to be significantly different for one mission application versus another.

Other neutron shield materials

There are many potential hydrogenous materials that could be considered for neutron shielding, but they are generally less desirable. Polyethylene (Poly) is a commonly used as a neutron shield in nuclear facilities, but it is not well-suited for most space reactor applications due to thermal constraints; i.e., a long-life operational temperature limit of $\sim 350\text{ K}$, plus poor thermal conductivity, irradiation tolerance, and strength. Other plastics, rubbers, or hydrocarbons have similar issues. Conversely, there are higher temperature hydride materials, e.g., ZrH_x or YH_x , which could achieve higher temperatures than LiH, but they are much less effective at shielding neutrons on a mass basis. They could be considered over LiH if extra gamma shielding and/or a slightly higher temperature were desirable; although these compounds, particularly YH, are not desirable from a capture gamma perspective. In situ regolith (dirt and rock) certainly has great potential on a surface mission, and this is discussed in depth later.

Gamma shield materials

Gamma neutron shielding is usually considered to be a high-Z material such as tungsten, lead, or depleted uranium, but any material can be effective. The majority of reactor gamma dose is often in an energy range where all materials have a similar mass attenuation coefficient; fission gamma dose is highest in the 1–5 MeV range. Shielding is mostly determined by the density-times-thickness ($\text{g}\cdot\text{cm}^{-2}$) of any material between the reactor and the shielded location. As a result, any “free” material (spacecraft components, structure, regolith, etc.) that can be placed between the reactor and the shielded location can be of great benefit. In some cases the advantage of high-Z materials is mostly that they can provide the more mass in a compact volume. However, there are other scenarios where a high-Z material provides a significant benefit. Any shield that contains significant ^{10}B will have a large amount of 478 keV gammas; high-Z materials have a much higher attenuation coefficient at this energy. High-Z materials are also more effective at shielding very high energy neutrons, $> 5\text{ MeV}$, but there are relatively few fission neutrons of that high energy; ironically most of the very high energy gammas come from capture in high-Z materials. The figure below shows the mass attenuation coefficient for potential shielding materials.

In many cases, capture gammas represent more of a shielding issue than fission gammas, because neutrons tend to penetrate further into the shield, and then create a high energy gamma near the back (downstream) end of the shield. In shielding terminology the ratio of dose from capture gammas to fission radiation is called the “buildup factor.” As discussed previously, it is desirable to have a neutron shield with strong neutron absorption, preferably an absorption that does not produce a high energy gamma. High neutron absorption is also important because it prevents capture gammas from being produced in the gamma shielding. If the neutron shield does not contain a strong neutron absorber, it is possible to place a small layer of $1/v$ absorber in front of (upstream) of the gammas shielding. A small layer (~ 1 mm) of B_4C can be very effective in reducing high energy capture gammas. Another option would be to use a layer of borated steel, which could also serve as a structural component and a heat removal path.

Shield design considerations

Shield design is not simply a neutronic exercise, nor should it be performed without being integrated with reactor and system design. The shield is often the structural foundation of the reactor power system, as well as the structural interface to the spacecraft. In those cases the shield should be a very robust component, in terms of surviving temperatures, stresses, fluences, etc. Thermal management can be a significant design issue, and will often drive the material selection as noted above. Thermal expansion must be considered with respect to all connections to the core, control drive motors and shafts, power conversion, etc. There also must be penetrations or slots for instrumentation cabling and coolant flow (or heat pipes). All of this must be done while creating minimal streaming paths for radiation through the shield. Finally, the shield must be practical from a fabrication, test, and cost perspective.

The relative level and balance of neutron and gamma shielding is highly dependent on mission and component requirements, the surrounding environment (e.g., space or surface), power level, spatial separation, etc. Some reactors require more neutron shield mass, while others might require more gamma shield mass. As mentioned previously, no material is distinctly a neutron or gamma shield. These terms are used to define the primary function; i.e., a neutron shield’s primary purpose is to shield neutrons and vice-versa.

As a rule of thumb, neutron flux needs to be reduced 2 decades (orders of magnitude) more than gamma flux from the reactor to a shielded area; this is component dependent, but is generally true for most materials as well as humans. This difference also depends on reactor spectrum; a fast spectrum reactor will emit a relatively higher ratio of fast neutrons to gammas, while a moderated reactor will emit a relatively higher ratio of gammas to fast neutrons (due to the differences in mass density and overall fast neutron flux).

Another generality is that it requires significantly more mass to reduce gamma dose by a decade (or any amount) than it takes to reduce fast neutron flux by the same amount. Very rough rules of thumb can be applied to common neutron and gamma shielding materials: ~ 4 cm of LiH/H₂O can reduce fast neutron flux by a factor of 2, while ~ 1 cm of W/U can reduce gamma dose by a factor of 2. One centimeter of W or U is $\sim 5 \times$ heavier than 4 cm of LiH or H₂O, so in this example gamma shielding would require $\sim 5 \times$ more mass than neutron shielding.

The combined effect of the generalities above is that reactors with very low shielding requirements (perhaps only to reduce neutrons by 3 decades and gammas by 1 decade) require almost no gamma shielding mass; in fact the neutron shield might provide enough gamma shielding in itself. Whereas a reactor with very high shielding requirements (perhaps to reduce neutrons by 8 decades and gammas 6 decades) will not only be thick and heavy, but most of the shield mass will be gamma mass.

As mentioned previously, no material is purely a neutron or gamma shield, which leads to a few other rules of thumb. LiH/H₂O provide $1 \times$ gamma shielding for every $5 \times$ of neutron shielding, and W/U provide $1 \times$ neutron shielding for every $5 \times$ of gamma shielding. Neutron shield materials like B₄C and Be are actually more like hybrid materials, because they can provide almost as much gamma shielding as neutron shielding. Of course, all of the rules of thumb provided above are highly generalized, and are dependent on every other aspect of shield effectiveness: including the level of streaming and scattering, the reactor spectrum, material density and composition, where this particular thickness is utilized within the shield, etc.

Relative shield material placement

There are several factors that determine the optimal placing of various neutron and gamma shielding materials relative to each other. Buildup factor, or the production of capture gammas, is often the most important of these design concerns. In this case, it is desirable to place most of the neutron shielding in front (upstream) of gamma shielding. However, neutron shielding is relatively thick, and the more that is used upstream the further the gamma shield moves back in the geometry. This creates a mass concern, because any realistic shielding geometry will have a radial component, such that size increases with further separation from the reactor. The two predominant examples of radial mass increase are moving backward in a shield cone or moving outward in a cylindrical or spherical surface shield component. Another factor that guides relative placement are the dose requirements of the shield materials. If LiH is used, it is often beneficial to place another material in front of the LiH to prevent swelling and high power deposition; this material could be a gamma shielding, or a most robust neutron shield such as Be or B₄C. Another placement consideration is heat removal and structure, which often leads to a layered shielding approach. Each shield layer might have ~ 10 cm of neutron shielding, followed by a ~ 1 cm of gamma shielding. This helps reduce capture gammas while also removing internal power generation, plus the downstream layers can sometime effectively shield the capture gammas generated upstream. All of this is application dependent, and must take into account the hybrid effect of each material (i.e., that all materials shield both gammas and neutrons to some extent).

Spot shielding

The term “shield” generally refers to the bulk shielding close to the reactor, which serves to reduce the radiation environment over a large volume. In some applications, there will be a component that is much more sensitive to radiation than anything nearby. In this case a small shield, or spot shield can be placed directly in front, or upstream of this component. Spot shielding works very well for gammas because they do not scatter very effectively; most dose comes the source point where the gamma was generated. The vast majority of gammas will originate in the reactor or shield (either by fission or capture), so they will all travel from a similar upstream direction. In addition, gammas can be shielded with thin layers of material (cm), thus gamma spot shielding can fit in potentially tight geometries in the payload region.

Spot shielding is rarely effective for neutrons. Neutron flux or dose can come from a scatter with any component nearby, thus a single directional shield does not work as well. As a result, the shielding in front a component needs to be a bit wider or slightly wrap around the component (as opposed to shielding solely in the primary upstream direction). This not only adds mass, but it introduces the potential for counterproductive scattering back into the spot-shielded component or any component nearby. Neutron spot shielding is also difficult due to the need for thick shielding (~ 4 cm for a factor of two vs. ~ 1 cm for gammas). It can become heavier with increasing diameter (if there is a radial component to the spot shield), and a thicker shield further increases the potential for counterproductive scattering.

In-space reactor shielding

Shielding in space is relatively straightforward because of the ability to shadow shield the reactor radiation. There is no natural path for radiation to scatter from the surrounding air, ground, building, etc., therefore anything behind the shield (or in its shadow) is protected. The shadow is generally in a conical shape, where the smaller diameter of the cone is near the reactor and the cone expands in area beyond the shield. The shield cone angle is determined by the diameter of the payload/electronics region and the axial distance from the reactor to this region. The axial separation has a major effect on shield mass for two reasons. First, the greater the separation the smaller the cone angle, thus the smaller the shield diameter. Far more important is the decrease in radiation intensity with increased separation. Beyond a few meters of separation, the drop in radiation intensity approaches the

$1/r^2$ effect of distance from a point source. Note that the $1/r^2$ effect only applies to radiation which originated from the reactor, scattered neutrons or capture gammas from the shield will require even further separation to approach the $1/r^2$ effect.

Most space reactor concepts utilize a boom to separate the reactor from the payload (or any sensitive components). From a shielding perspective, the longer the boom the better, but there are many limiting factors. If a non-deployable boom is used, the separation distance is limited by the launch vehicle shroud, which is rarely optimal because it requires a very high mass shield. A deployable boom introduces several complications, including the unfurling of cables and potentially coolant lines that extend along the length of a spacecraft. The longer the boom, the more difficult it is to package everything in a small volume and successfully deploy it. The other concern is structural, because the moment of inertia increases with the axial distance squared; thus as length increases the boom mass per unit length will increase and spacecraft maneuverability will be hampered. Many historical concepts have considered deployable booms in the ~ 10 – 20 m range, but recent technology improvements might allow $\gg 20$ m booms, which could allow very low shield masses. Boom length is one of many variables to be optimized as part of an integrated shielding solution. Some other variables, as discussed previously, are mission length, component rad-hardness, power level, axial reflector length, and material selection.

In a shadow shield configuration, the primary purpose of neutron shielding is to scatter neutrons to a new trajectory that will not hit the shielded region: referred to as a “productive” scatter. Unfortunately, after a productive scatter has occurred, there is always a chance that a “counterproductive” scatter will occur; i.e., a subsequent scatter that retargets the neutron so that it will hit the shielded region: this is referred to as a “recoup-scatter.” The net effect of these two scatters is diminished to only the decrease in neutron energy. Recoup-scatter can be important in optimizing the shield, in particular around the perimeter on the far (downstream) end of the shield. Material in the back corner of a shield cone can cause enough recoup scatter to substantially offset any productive scatters that might occur, thus the mass of shielding in that area may not be justified. In some cases a portion of the shield geometry might actually increase dose, e.g., recoup-scatter dose outweighs the effect of productive scatter, so clearly mass should not be placed there. The potential for recoup scatter also makes segmented shielding less attractive; i.e., placing a void or gap between two or more neutron shields.

Another integrated design consideration is to optimize the component layout in front and behind the shield, to place as much mass between the reactor and sensitive components as possible. Concepts with an intermediate heat exchanger (HX) can easily gain a shielding benefit via HX placement. Brayton and Stirling components can be used to shield downstream components, but they also need to be positioned to minimize their own internal dose. First order, the goal is to use one component to create small shadow shield for others downstream. This works well for gammas, because it is not very effective for neutron shielding because of multi-directional and recoup-scatter. Also, if there are voids or gaps in a component or subsystem it might leave a streaming path for a hot spot in a downstream component; although any material will generally reduce the average flux/dose downstream.

Penetrations through the shield for the coolant pipes, control shafts, cables, etc. can be a major design issue due to radiation streaming. In many cases the gaps and insulation around the penetrating components are more of a streaming issue than the components themselves; depending on whether the pipes are empty (e.g., filled with gas/vapor instead of liquid metal), and how much insulation and fabrication/expansion tolerance (gaps) is needed between then components and shield. The latter is an important design consideration that balances shielding, mechanical design, thermal design, and potentially reliability. Features that create direct/straight streaming paths are of the greatest concern, so it is usually desirable to use staggers, kinks, bends, spirals, etc. to prevent a straight line-of-sight for radiation. However, any non-linear design feature will almost always add cost and complexity to any component, as well as system integration and assembly issues. Shield construction and integration will usually be much simpler with straight penetrations, and coolant tubes and heat pipes themselves will be simpler (although in some cases a bend in pipes is desirable to create a spring effect to accommodate differential thermal expansion). The magnitude of a streaming depends largely on the solid angle (path area divided by path length) and what the upstream end of the path “sees” (i.e., does the streaming path emerge from the core, does it view fuel, reflector, vessel, or space?). The significance of streaming depends substantially on how many orders of magnitude the shield reduces radiation. If the shield reduces gammas by only 2 decades, then a modest amount of streaming is of minimal consequence (except for the small region in the line-of-sight of the streaming path). If the shield reduces gammas by 6 decades, then even a small level of streaming can dominate dose globally and locally.

Any shadow shielded system will have to evaluate the pros and cons of placing some components outside of the shadowed area: e.g., radiator, coolant pipe, satellite dish, probe, robotic arm, etc. It may be easier to engineer a system with coolant pipes outside the perimeter of the shield, but that would have to be weighed against the added dose from radiation scatter from the pipes. There are many options of where to position and how the potentially coil pipes around the shield, or in grooves on the outside of the shield. The biggest potential design decision with respect to external scatter is the position and geometry of the radiator panels. If a large area of radiator is positioned outside of the shield cone angle, it is possible for the neutron dose scattered from the radiator to be higher than the dose coming through/from the shadow shield. The significance of external neutron scatter also depends greatly on how many decades of shielding is utilized.

Surface reactor shielding

Surface reactor shielding is quite different from a space power mission, where a shadow shield can be used. This is because scattering from the regolith and surrounding spacecraft components usually require some shielding around the entire reactor, commonly referred to as “4pi” shielding. A 4pi shield does not imply the same shield thickness in every direction, rather the optimal amount

in every direction to achieve a combined set of shielding goals. The shield will generally be thicker in the direction of components, electronics, and human areas. The ground or regolith is shielded to balance the neutron scatter than reaches all of those regions. If the shield design is non-cylindrical, e.g., thicker in the azimuthal direction of the human outpost, then it is sometimes referred to as a “shaped shield.” One of the biggest challenges of surface reactor design is balancing all requirements, which can include:

- Cumulative dose to power conversion and other reactor components.
- Power deposition to reactor components, spacecraft, and surroundings.
- Dose rate and cumulative dose to all electronics and sensitive components.
- Dose rate to infrastructure elements: e.g. rover charging, propellant production.
- Dose rate to human outpost.
- Activation dose to humans for near-reactor operations.

The need for 4pi shielding can make surface reactor shields very heavy, and they can dominate the system mass. Fortunately there are many potential options for using in situ resources as shielding materials, which can provide substantial mass savings. Regolith could be used in several ways: berming, sandbagging, digging/burying, using natural topography (e.g., craters or ridges), or any combination of these. In-situ resources could also be used to fill permanent structures or cans as a fixed part of the reactor structure (e.g., sand could be scooped or vacuumed), and in the best scenarios in situ water could fill shield tanks or perhaps concrete could be made. All shielding options that require in situ resources will depend on significant robotic ability (or existing robotic/human infrastructure) to successfully complete the mission. Many of these options could add significantly to mission risk, but the mass savings potential is so large that in situ options always warrant serious consideration. Any option that can pre-deploy and verify in situ shielding prior to human mission departure would have a significant advantage.

Regolith as shielding

Regolith is a blend of soil and rocky debris that covers the surface of the moon, Mars, and most asteroids or planetary bodies. On the Moon and Mars regolith is predominantly in the form of metallic-oxides. The composition of regolith, primarily oxygen and silicon, makes it a very effective at scattering neutrons, which makes shadow shielding impossible if regolith is nearby. If regolith is within a few meters of the reactor, e.g., the ground, then regolith scatter can dominate and otherwise well-shielded system; thus the need for 4pi shielding to reduce scatter from the ground. Regolith composition varies between the Moon and Mars, more so in different regions on the respective surfaces. The table below shows various regolith compositions ([Heiken et al., 1991a](#); [De Angelis et al., 2004](#)).

Regolith Mass Fractions				Regolith Atom Fractions			
	Lunar Mare	Lunar Highlands	Mars		Lunar Mare	Lunar Highlands	Mars
SiO ₂	45.34	44.65	49.16	O	60.57	60.94	62.65
Al ₂ O ₃	15.13	27.09	8.38	Si	16.93	16.12	17.96
FeO/Fe ₂ O ₃	13.47	5.06	18.44	Al	6.65	11.53	3.61
CaO	11.19	15.58	6.26	Ca	4.47	6.03	2.45
MgO	9.68	5.66	7.82	Mg	5.40	3.05	4.26
TiO ₂	3.62	0.54	1.23	Fe	4.20	1.53	5.07
Na ₂ O	0.50	0.46	2.35	Na	0.36	0.32	1.66
Cr ₂ O ₃	0.31	0.33		Ti	1.02	0.15	0.34
K ₂ O	0.27	0.17	0.34	Cr	0.09	0.09	
P ₂ O ₅	0.25	0.11		Mn	0.06	0.09	
MnO	0.18	0.30		K	0.13	0.08	0.16
SO ₃	0.05	0.07	5.47	S	0.04	0.05	1.50
Cl			0.56	P	0.08	0.03	
				Cl			0.35

The tables above show that the regolith on Mars and two different locations on the Moon are rather similar. From a neutronic perspective, the biggest difference is that Mars has more neutron absorbing material; thus it will normally not scatter back quite as

many neutrons, with a corresponding small increase in capture gammas. The average particle theoretical density is ~ 3.1 g/cc on Mars, ~ 3.2 g/cc in the Lunar Highlands, and ~ 3.4 g/cc in the Lunar Mare. The bulk material density will be much lower than these values depending on the packing fraction of the particles in the regolith. A good initial for the actual, undisturbed density of regolith (65% packing of 95% TD particles) might be ~ 2 g/cc. In most cases, the density very close to the surface will be slightly lower than the average; the moon has a surprisingly low-density layer on top. The natural packing fraction (density) will be location dependent, but in many cases the density will be affected by human activity; e.g., when containers are filled, holes are refilled, or the ground is compacted.

Overall, there is not too much difference from a shielding perspective between the regolith on the Moon and Mars, but there are some environmental differences. The atmosphere on Mars creates an interesting, and sometime negative scattering effect. Topography can play a major role in the shielding solution, and in some cases the spherical curvature of the bodies can also play a role. These impact of environmental differences is discussed further in the sections below.

Buried reactors

Burying the reactor within the regolith is generally the lowest mass shielding solution for any application that requires a permanent human presence nearby. The mission advantages of a buried reactor are substantial, including the potential to place the outpost and equipment < 100 m from the power system and to approach the reactor for maintenance/repair with minimal radiation risk. Both of these advantages depend on the hole depth. Any depth that covers part or all of the core is very valuable, and 1 or 2 m of depth is all that is needed to provide most of the advantages. If the reactor is buried several meters deep, then it may be possible to allow human activity above the reactor even while operating at full power.

Another small advantage of a buried reactor is that it can be left in place after operation, either after its nominal operation or a potential failure. Although, this advantage is rather small because it is unlikely that any above-surface reactor would have to be moved/buried as part of decommissioning. The dose surrounding a space reactor will become insignificant months after shut-down, so the only risk is release of radioactive material into the environment. Even then, the potential radiation release will be orders of magnitude lower than that from terrestrial power plants (due to lower power), so a potential exclusion after a release zone might be tens of meters instead of tens of kilometers. More importantly, environmental contamination will be much less of a negative on the Moon or Mars because no one will be breathing the air; contamination of various regions would have to be considered, but will likely be negligible. Therefore, there should be minimal risk of leaving an above-surface reactor in place indefinitely.

The difficulty of buried reactors is that they require considerable infrastructure. The capability is required to dig a hole, remove, transport, and position the reactor in the hole, potentially refill the hole, and if possible compact the refilled regolith. These actions need to be performed reliably while also not damaging the power system. Expediency might also be an issue if the operation requires installation during a lunar day or a fixed amount of battery power; although if the infrastructure is available to bury the reactor another power system will likely already be in place.

The key to successfully burying a reactor will be to dig in a region with sufficiently deep loose regolith; i.e., where the depth above the bedrock (or whatever hard surface exists) is greater than the intended hole. A study by Wilcox et al. (2005) investigated several regions, and noted that lunar regolith depth varied between 2 cm and 40 m, with significant local variability. Heiken et al. (1991b) states that the regolith is generally about 4–5 m thick in mare regions and 10–15 m in highland areas, which provides plenty of margin for digging a hole. Also, more information on lunar and Mars regolith composition will certainly be obtained in the relatively near term. Hopefully, before a buried reactor is deployed, there will be enough infrastructure to scout out appropriate sites before digging begins.

There are several possibilities for the geometry of the hole in which the reactor is buried (e.g., trench, slot, hole, etc.). Each technique has pros and cons from an architecture and energy perspective, but from a shielding it is preferable to leave as regolith next to the reactor undisturbed. Refilled regolith will have significantly lower density, depending on how much effort is used to try and compact it, which will allow more neutrons to leak to the surface and potentially create dose to any region. Each method of creating a hole will have a different profile of undisturbed regolith and refill density, and more importantly potential hole depth for a specific region and application. In many respects, auguring a hole might be a preferable option, because it leaves surrounding regolith undisturbed, creates a small berm with the expelled regolith, and might be the easiest tool to use (assuming enough power can be provided). It is also possible to consider burying a reactor in a horizontal configuration, if a trench is easy to dig and refill, but this generally adds significant complication to system design.

There is one other significant engineering issue of a buried reactor—thermal balance. Regolith is a very poor heat conductor, both the rocks/particles themselves and more importantly the gaps between them. The conductivity is even lower on the moon because of the lack of atmosphere to facilitate heat transfer. This is a problem because if environmental heat removal is unavailable, then the system design cannot take advantage of the environment to reject secondary heat (from reflector, shield, components, and potentially decay heat). In this case secondary heat would have to be rejected either by the primary heat removal system or an additional dedicated one. If the primary coolant system is used, then all of the ex-core components must run hotter than the reactor coolant. If a dedicated system (sometime referred to as a cavity cooling system) is used, then the peripheral components can run cooler, but an entirely new subsystem must be engineered, assembled, and installed.

Ironically, the biggest thermal concern can be the temperature of the regolith itself. The idea of a buried reactor is to minimize shield mass, which means placing regolith as close as practical to the reactor. In some cases this can cause the power deposition in

the regolith to be so high that it cannot be conducted out (either back to the reactor cooling system or to the surface). The temperature limit of the regolith will depend on many factors, but a reasonable assumption might be ~ 1000 K, or a temperature close to what the reflector and shield would operate. This design scenario would probably call for a high temperature reactor shield (B_4C or Be) as opposed to LiH or H_2O . When the regolith gets hot, it may be that the regolith will sinter, and thus increase the conductivity to a level where overheating would not occur. Although it would be hard to verify if and when sintering might occur, plus the sintered material might crack, which would once again reduce conductivity and perhaps leave radiation streaming paths to the surface. Also, very hot regolith might off-gas materials that could attack the reactor system. If the regolith gets too hot it will lose structural and/or shielding integrity and ultimately melt. In cases where the power/flux is high enough to overheat regolith, there are two options. The first is to include additional shielding in the reactor design, i.e., use reactor shield material to shield the regolith. The other option is to include even another heat removal system; i.e., one that is placed in the regolith to transport power from the regolith to the surface. The most difficult place to keep regolith cool might be the lower radial region surrounding the core, or perhaps below the reactor, depending on local power density and heat transfer paths.

Shielding the axial region above the reactor in a buried configuration involves a lot of design trades. It might be desirable to save additional mass by inserting regolith into the gaps between the reactor and power conversion system, but this may introduce significant thermal and shielding uncertainties. If the hole is deep enough, it might be desirable to leave an open cavity in part of this axial region above the core, to minimize launched mass and/or simplify thermal management, and use a “plug” shield at the top of the hole. Finally, if a horizontal configuration is considered, as opposed to vertical (assuming the reactor is roughly cylindrical), the problem of thermal management becomes even more difficult.

Above-surface reactors

Early surface reactor missions may not have the ability to bury a reactor. Initial reactor missions will likely be needed to provide power for the building of the required infrastructure, or perhaps early missions will be purely robotic missions or technology demonstrations. The brute-force solution is to launch every kilogram of shielding from Earth, which is practical for a small robotic mission, but undesirable for a human mission. However, there are still plenty of ways that an above-surface reactor can utilize regolith and topography to substantially reduce system mass.

From a reactor perspective, the easiest way to provide in-situ shielding is to use topography. The reactor could be landed in a crater or on the other side of a ridge from the outpost location. This method is becoming increasingly attractive as the technology improves for precision spacecraft landing, as well as the ability to create detailed mapping of potential reactor and outpost sites. The drawback of this approach include the potential difficulty to route/connect the electrical cabling, and scatter from surrounding ridges/features/air back to the spacecraft or to the outpost (i.e., scatters that circumvent the primary topographic shielding).

If a natural topographic feature is not available, it is possible to create a manmade shield, or berm, between the reactor and outpost. A berm can be constructed by a bulldozer and/or backhoe, by stacking of locally made concrete, sandbags, or containers filled with regolith/sand, or simply rock-by-rock by a robot or human. This wide variety of options offers great flexibility, and methods can be utilized to best integrate with the existing and proposed infrastructure, as well as the mission architecture.

One of the biggest variables for an above-surface is how high the final reactor position is off the ground. From a shielding perspective the best configuration is to place the reactor on the ground. Shielding mass can be reduced by the elimination of the bottom shield. In addition, berm construction can be simplified by lowering the required height, or even better if topography solution can be enabled. The curvature of the Moon is so high that distance can help reduce line-of-site, but the distance would have to be relatively large. Great benefit could be provided if the reactor could be placed several km from the outpost. At 3.7 km of separation the curvature would cause a line-of-site deficit of ~ 4 m, which would allow a person standing at the outpost to be shielded from direct radiation up to a height of ~ 2 m on the power system. On Mars, the distance to achieve ~ 4 m of deficit would be ~ 5.2 km. Of course these curvature calculations assume a perfectly flat surface (actually a perfect sphere). Ultimately topography will dominate line-of-site and curvature might provide an additional small benefit, especially because several km of separation will be a difficult task on early missions. Ultimately, if advanced architectures could allow a separation of 10 km then curvature might dominate: the Moon would provide ~ 29 m of curvature deficit and Mars would provide ~ 15 m enough to allow even tall structures to remain shielded.

Unfortunately, placing the reactor on the surface will require the capability to lower the reactor from the reactor deck to the ground, or the infrastructure to remove the reactor and place it elsewhere. If the reactor cannot be lowered to ground level, there are many factors to consider. Constructing the berm, or using topography may become increasing difficult as the required height increases. If the reactor remains at a height of several meters or more, then the preferred option might be to try to install regolith around the reactor in place. Pre-formed or deployed containers could be filled by human and by robotic means (e.g., conveyor belt, vacuum hose, robotic arm, shovel/bucket, etc.). Alternatively sand bags or pre-formed in-site concrete could be stacked. These methods will be highly dependent on location, infrastructure, and lander design. One potential consequence of placing regolith close to the reactor is thermal balance; generally not as difficult as for a buried concept, but still a significant engineering design issue. The height of the reactor off the ground has several other design impacts, in addition to line-of-site. The closer the reactor is to the ground the more power deposition in the regolith, and warmer regolith is generally undesirable from a heat rejections perspective (although warmer regolith might help keep certain components from freezing overnight). The biggest effect of reactor height is on dose to the power conversion system and anything on the lander. If the reactor is very close to the ground (~ 1 m or less), there is some benefit because much of the ground scatter will return directly to the lower shielding. If the reactor is very high off

the ground ~ 4 m or more then the ground scatter paths become long enough that dose from the ground to the spacecraft is significantly reduced. As a result, there is generally a worst case height from a shielding perspective, which must be balanced with all other considerations. The inclusion of all spacecraft components (e.g., rockets and tanks) into the shielding solution is also important.

Skyshine on Mars

Skyshine is a shielding term that represents radiation that is scattered or created in the sky/air that eventually reaches a shielded area. On Earth, the atmosphere is relatively thick and provides enough shielding such that Skyshine is only a potential issue within $\ll 1$ km of a radiation source. The mean free path of a fast neutron in the low-density Mars atmosphere is ~ 1 km, and the bulk of the atmosphere is composed of two very effective neutron scattering elements—C and O. Therefore, any escaping neutron from the reactor can reach any location within a km or two from the reactor via only 1 or 2 scatters. For some bermed/topographic reactor shielding solutions on Mars, Skyshine can actually dominate the dose delivered to the shielded area. This can especially be the case if a reactor is placed horizontally (or anything other than vertical) on the surface. If Skyshine is significant, then additional 4pi shielding would be needed, mostly for regions facing the sky, although significant dose might also come from neutrons scattered off of the ground and then the sky. As distance increases beyond several km, then the shielding effect of the Mars atmosphere can provide more benefit than the negative provided by Skyshine.

Outpost separation

As indicated above, an important trade for an above surface reactor is the separation from a potential human outpost. The bulleted list at the start of this section shows that the dose to humans at the outpost is only one of several shielding concerns. In most cases, a good amount of 4pi shielding will be needed to meet other dose requirements, so the design question is: how much additional mass and/or construction work (burying, moving, berming, etc.) will be needed to accommodate humans at the outpost. Separation is a very useful shielding mechanism due to the $1/r^2$ effect. A typical design trade might consider the following: (1) separate 3 km without any additional shield mass, (2) separate 1 km with extra mass for shaped shielding, (3) separate 500 m with regolith installed on the lander, (4) separate 250 m with an on-surface configuration and a berm (or topographic feature), (5) separate 100 m with 1-m deep buried reactor, or (6) zero separation with a 4-m deep buried reactor. There are dozens of possibilities, and each will be mission dependent.

In most cases, a separation of a few km would be ideal except for one factor—the need to carry electricity from the reactor to the outpost. Power beaming will not be practical for surface reactors for decades, perhaps ever; thus a traditional power cable will be needed. The further the distance, the greater the concern of losses due to electrical resistance. There are two options to mitigate losses, (1) heavier cables with more conductive area or (2) using transformers for increasing the transmitted voltage (like what is done on Earth). Both of these options can make the mass penalty of a $\gg 1$ km separation greater than the shield mass savings. This issue adds another layer of complexity in determining the appropriate reactor separation for a specific mission.

The table below summarizes one example of a shield architecture trade based on the use of four 10 kWe Kilopower reactors on the surface of Mars (Poston et al., 2016). In column four, PMAD is the power management and distribution system, which is mostly electrical cable mass.

	Total Shield (kg)	Ave. Unit Shield (kg)	Instrument Distance (m)	Outpost Distance (m)	Low-Volt PMAD (kg)	Electric Power (We)	Total Mass (kg)	Specific Power (We/kg)
Left on Lander “as is”	2424	606	160	2000	1865	33.5	7989	4.2
Placed on Surface	2022	506	140	2000	1865	33.5	7587	4.4
Bermed/Topographic	1952	488	~ 50	~ 500	700	38.0	6352	6.0
Buried 75-cm-deep hole	1600	400	~ 25	~ 200	600	38.5	5900	6.5
Buried 150-cm-deep hole	1248	312	10	80	500	38.8	5448	7.1

The table above is a conceptual un-optimized study, but gives the flavor for the types of surface shielding trades that can be considered (note that the bermed/topographic case assumes the reactor is on the ground). This still only represents a small fraction of options, as it doesn't include the option of using regolith to surround the reactor on the lander, or use voltage transformers, include curvature effects, consider other materials, use regolith for axial reactor shielding, etc. Most importantly this chart does not spell out all of the individual design complexities and risks associated with each option; nothing should ever be decided solely based on numbers on a spreadsheet.

Radiation exclusion zones

Any time a reactor is used in the presence of humans there will be regions where an astronaut should limit time spent. Every one of these regions should be designated on an ALARA basis. The outpost or living quarters should be separated and/or shielded to lower the reactor dose to acceptable human levels; not necessarily as low as the 5 Rem/year used on Earth, but something that balances the benefits of the reactor (a capable and reliable power supply) versus the risk. Even if a restrictive 5 Rem/year is designated for the reactor, a large fraction of the reactor radiation can probably be shielded by the habitat, by the proper placement of any possible material between the reactor and regions where the astronauts sleep, eat, meet, etc. The difference between reactor radiation and GCR is that it can be shielded by any thickness of any material. If the dose in the habitat could be reduced by an order of magnitude (the equivalent of few inches of Al or regolith), then the reactor dose rate in the outpost region could be allowed to be closer to 25 Rem/year (similar to the GCR dose on the Moon or Mars), but only provide ~ 5 Rem/year to the astronaut assuming they spend 20 h/week performing EHA (extra-habitat activities) on the outpost grounds. Frequent outdoor work locations could perhaps be set up on the downstream or far side of the habitat (or on the far side of a ridge or manmade berm, etc.) to reduce EHA dose rate as well. Activities in the region surrounding the reactor (inside of the outpost distance) should be limited based on their importance. If a region of interest or infrastructure is half way between the outpost and the reactor, then the dose rate will be $\sim 4\times$ higher, but not of substantial risk for operations that might take a few of days of work. If an operation requires humans very close to the reactor, then it might limit time to an hour or two, or the reactor power could be significantly reduced to allow more time. If work is required on the power system itself (e.g., leak repair, component replacement) then the reactor would preferably be shut down and allowed to cool (radioactively) for a while; although if the power from the reactor is required to sustain life, then any potential dose would be acceptable to try and fix it. If shaped shielding is used to reduce reactor dose in the direction of the outpost, then an exclusion regions/rules would be azimuthally dependent.

Activation dose

The dose surrounding a reactor is highly dependent on its operational status. Prior to operation the radiation field from the reactor is negligible, and no shielding of the reactor of any kind is needed. During powered operation the reactor requires considerable shielding, unless humans are stationed many hundreds of meters from the reactor. After reactor shutdown, the dose environment immediately drops by at least 1 order of magnitude, and then drops off quickly from there (depending on the materials in the reactor, shielding and surroundings). In addition to decay radiation coming from the reactor core, there are also many potential activated materials that could provide dose to humans. This includes the nearby regolith, spacecraft, and reactor materials.

The activation dose depends primary on two factors: how long the reactor has operated and how long it has been shut down. The table below provides an example of dose rate surrounding a 40-kWe NaK-cooled reactor that is placed into a 1.5 m deep hole on the Moon (Poston et al., 2010) (technically not buried, because no regolith is backfilled on the top). The dose rate shown is to a person standing on the ground directly adjacent to the power conversion system (1 m from the core radial center), perhaps performing repairs.

> 10 rem/hr <i>leaving only</i>	> 1 rem/hr <i>mission critical ops?</i>	> 100 mrem/hr <i>maintenance ops?</i>	> 10 mrem/hr <i>> lunar background</i>	< 10 mrem/hr <i>< lunar background</i>	< 1 mrem/hr <i>negligible</i>	< 0.1 mrem/hr <i>Earth background</i>

The table above shows that the dose after shutdown can come from several sources, and the dominant source can change with operating and shutdown time. The text in italics shows the primary contributor and the fraction of dose it contributes. One day after shutdown the dose from the NaK coolant in the piping provides most of the dose, regardless of operating time. If the reactor has operated 8 years, then the Ni in the In718 (the Inconel 718 used in the Stirling engines) dominates dose after the reactor has been shutdown more than 2 weeks. Ironically the fuel itself only dominates dose in a few scenarios, weeks after shutdown.

The key point of the table above is that it is not unreasonable to assume maintenance could be performed on the system, except for the core itself (which in most cases should be highly reliable). Any above ground component (Stirlings, motors, piping, radiator, etc.) can be safely approached and repaired after perhaps a 1 day cooldown period, and in an emergency situation repairs could be performed almost immediately after shutdown without acute radiological consequences. However, this is a very specific case and all reactors and applications will be different: e.g., an above ground reactor would likely increase regolith/fuel dose, or many reactors will not use NaK and/or Inconel, etc.

Summary

Shield design and integration for space reactors is rarely a simple task. The shield's primary purpose is to reduce the dose from neutrons and gammas to specific regions; however, the modeling and calculation of radiation transport is usually the simplest part of shield design. The low mass and volume constraints for a space reactor can create significant thermal balance and structural issues. High temperature and low mass can lead to the use of materials with little experience/infrastructure or confidence in lifetime performance. The requirements for shielding are highly dependent on the mission goals, architecture, and environment. Shielding for in-space reactors presents considerably different issues than for surface reactors. There are many options for using in situ materials for surface reactor shielding, with the ideal case being able to use topography (ridges, craters, etc.) to perform the bulk of the radiation shielding. Regardless of the approach, a reactor can be used on a human exploration mission without adding considerable risk or limitations to the astronauts. Furthermore, the robust power-rich capability of fission reactors will likely make astronauts safer and more flexible/capable than any other power alternative.

Attributes of a Kilopower reactor

Fig. 1 shows the basic layout of a 1-kWe in-space Kilopower system. The basic Kilopower reactor components are the fuel, heat pipes, control, reflector, and shield. The Kilopower system includes the reactor plus the Stirling power conversion system and the radiator (plus other sub-components). The 1-kWe reactor core (fuel) is only 11 cm in diameter and 25-cm tall. Eight Haynes230 heat pipes are placed in slots on the outside of the fuel, and are held in place by Haynes230 clamping rings via an interference fit. The heat pipes, which nominally operate at 800 °C, use sodium as the working fluid and include a nickel mesh wick in the evaporator region. The heat pipes transport heat to the hot-end of eight Stirling convertors, which are cooled on the cold-end by a titanium/water radiator. The in-space power system design is very similar to a surface reactor system (e.g. for Moon or Mars) except for the layout of the shielding and the radiator. Higher power systems will have larger Stirling engines, increased radiator area, more heat pipes, etc., with only a modest growth in core size.

Each Kilopower component, and how they integrate together, is simplified by low power; e.g., at low powers (<100 kWt) thermal management and irradiation damage of components do not complicate system design. The simplicity of the system also leads to high reliability. The reactor is essentially solid-state, with the control rod being the only moving part. Actually, at low powers (~10 kWt) the burnup effect on reactivity is so small that long lifetime (10+ years) could be achieved without any control movement after startup; higher power systems would require occasional (monthly or annual) control movement to maintain reactor temperature. At all power levels, Kilopower systems can survive worst case transients (e.g. loss of heat removal by Power Conversion System (PCS)) without any control action. The lack of need for real-time reactor control greatly simplifies system control. The Stirling controller can independently control the reactor/system power level, without potential interference and interactions caused by a separate control feature associated with the reactor. The “reactor” control system only needs to move the control rod at startup, and whenever a boost in reactor temperature is desired—this could possibly be done remotely when deemed necessary by a ground engineer, and thus not require any automated control software.

The Kilopower reactor concept is one of the simplest space power reactor concepts ever proposed. Perhaps the most important “simplicity” of the system is in neutron kinetics and system dynamics. The kinetics of a compact, fast reactor are dominated by one factor—changes in material density/geometry (changes in neutron interaction rates, i.e., cross sections, have small effects). The Kilopower solid core eliminates potential movements of fuel rods/pieces relative to others, and the surrounding geometry is fixed (except for small potential relative movements due to thermal expansion), thus the only major reactivity effects are changes in neutron leakage due to material expansion. This makes the startup and operational system dynamics easy to predict/verify.

Another system attribute that leads to high reliability is inherent redundancy in heat transport. Each heat pipe is an independent, highly reliable mechanism. In all proposed Kilopower systems, full power can be delivered even with several heat pipes or Stirling engines failed. If three heat pipes fail that are directly adjacent to each other, then power level may need to be reduced to avoid exceeding the fuel temperature limit (assuming that heat pipe failures can be diagnosed). The baseline

Fig. 1 1-kWe Kilopower system layout.

Kilopower power conversion approach is to attach a single Stirling engine to a single heat pipe—referred to as the 1-for-1 approach. This was the configuration used in KRUSTY, which provides the simplest suite of technologies, the simplest system dynamics, and the highest efficiency (i.e., smallest temperature drop). The 1-for-1 configuration requires a large number of small engines, which may or may not be optimal from a cost and development perspective. One negative of this approach is that if a Stirling engine fails, it effectively fails a heat pipe in the core, whereas an intermediate heat transfer mechanism would eliminate this problem. However, the 1-for-1 approach provides a reliable diagnostic of heat pipe failure, which will allow mitigation of worst case failure patterns if they indeed occur (noting that the probability of heat pipe failure will likely be much lower than that of a Stirling converter).

Kilopower reactors should also be very reliable with respect to launch and landing loads. A solid block of fuel eliminates potential fuel-pin, grid-plate movements. Heat pipes should also be less fragile than the alternative—coolant piping to and from the reactor, including connections to other loop components; plus, the piping and connections will likely provide a single point failure. The Kilopower project has started to evaluate launch loads and the system appears robust.

Finally, the compact reactor size allows for a simple approach to launch safety, transport, and nuclear and non-nuclear system testing. Kilopower reactors are essentially non-radioactive prior to operation. The only condition that can create a significant nuclear hazard is an inadvertent movement of the control rod that causes criticality. There is no conceivable launch or transport accident (including water, wet-sand, etc.) that can cause criticality unless the rod is removed. More so, the system will only go critical if the rod is removed and the radial neutron reflector is geometrically intact. It is unlikely that any impact strong enough to remove the rod will not also remove, or least significantly crack/deform the radial reflector, and system design can help ensure this. Therefore, the only significant nuclear safety engineering required for Kilopower is to ensure the rod does not move unless it is properly commanded to do so (a feature that any reactor must have by definition).

The mass of a Kilopower system is highly dependent on the application (power level, lifetime, environment), the risk tolerance of the customer (e.g. level of redundancy and margin), and can change substantially due to shielding requirements (in-space or on-surface, separation distances, rad hardness, etc.). The table below shows a range of masses for Kilopower systems designed to operate 10 years at full power with a typical shield mass. Space reactor shielding is discussed in-depth in [Poston \(2021\)](#).

<i>Kilopower system</i>	<i>Mass</i>	<i>Specific power</i>
1-kWe HEU	400 kg	2.5 We/kg
10-kWe HEU	1400 kg	7.1 We/kg
10-kWe HALEU	2200 kg	4.6 We/kg
30-kWe HALEU	3500 kg	8.6 We/kg

The mass estimates could be higher or lower based on the aforementioned factors (especially shielding), but the uncertainty in mass for a specific application should be relatively low due to the simplicity of Kilopower, and comparison to the successful Kilopower Reactor Using Stirling Technology (KRUSTY) test. KRUSTY was tested with HEU (93% enr. U), but in some cases HALEU (19.75% enr.) might be preferred for non-technical reasons. Kilopower reactor core lifetime is limited by fuel swelling criteria, which is a function of fuel burnup (fraction of uranium atoms fissioned). The HALEU systems have substantially more uranium mass, and therefore much lower burnup at a given power level. This is why the HALEU system can be designed to much higher power levels than the HEU system. Note also that technical risk increases slightly with higher power for all concepts.

Origins of the Kilopower concept

Early push for a simple concept

By the early 2000s there was a realization that previous space reactor programs had reached for advanced concepts that could not be readily built without significant investment in both research and facilities ([Poston, 2002](#)). These programs typically called for:

- Designs using materials for which little or no data existed requiring extensive research and development;
- Designs with uncharacterized physics that required research to verify;
- Designs with advanced fuels that required investment in fuel research and testing, new production facilities or alternatively new production lines in existing facilities; and
- Designs requiring significant ground testing of the reactor in new test facilities to prove out the advanced concept.

The programs had schedules of a decade or more and cost estimates for a completed space reactor in the billions. Given the time and cost for the programs, Congress did not have the patience to fund them until completion (an example is presented in the GAO report on the SP-100 program ([General Accounting Office, 1992](#)). After approximately a dozen failed space reactor projects this situation led to many space reactor enthusiasts to call for a simpler concept that could be built in a reasonable amount of time and for a reasonable cost.

2010 Fission study for gas giant decadal survey

In 2010 as part of the Planetary Science Decadal Survey for gas giant planet missions, a simple small fission power system for space was evaluated. The study was documented in the 2011 report “Small Fission Power System for NASA Planetary Science Missions (Mason et al., 2011).” The report outlined a concept for a simple low power reactor. The reactor was assumed to have a small metal-fueled core, about the size of a coffee can, and was cooled by liquid metal heat pipes. Two version of the reactor were proposed, one with thermal electric power conversion and one with Stirling engine power conversion. The reactor thermal power was set at 15 kWt, such that the reactor using thermal electric power conversion would produce 1 kWt of electricity and a version using Stirling engine power conversion would produce 3 kWt of electricity. The goal was to produce a reactor that could be built and tested easily and cost effectively. As the report states:

At this scale, numerous test facilities exist within the NASA community to conduct thermal- vacuum performance and mechanical vibration testing. The reactor fuel can be fabricated in existing production facilities, and the reactor neutronics can be verified in existing nuclear criticality test facilities within the DOE complex.

The report concluded that this low risk reactor concept could be built and be readied for flight in 10 years or less. The only criticism of the concept was that a heat pipe reactor had never been built and tested. This criticism would be addressed by the eventual DUFF and KRUSTY tests.

The reactor was not given a name until after the completion of the report, but the NASA program lead named the reactor concept “Kilopower” and the name would stick for the rest of the program.

Beginnings of the DUFF test

In the winter of 2011 LANL staff began to explore how to build and test a Kilopower reactor concept. Based on the design from the 2011 study, the thermal power was lowered to 4 kWt from 15 kWt. The Stirling engine version was embraced over the thermal electric version. By going with the Stirling engine version, the 4 kWt reactor would produce ~1 kWe. This smaller version was deemed even easier to build and test.

Conversations were then started with the LANL critical experiments facility staff located at the Nevada National Security Site. A prototype reactor would need to go to peak temperatures of 800 °C. However, the critical experiments facility regulatory limit on excess reactivity limited reactor temperature to 300 °C. Also, a prototype reactor was more expensive than could be done for the limited budget the LANL team thought could be secured through internal R&D funding. A compromise was proposed to use an existing critical experiment reactor, called Flattop, to run at 300 °C and power a small low temperature Stirling engine using a water heat pipe. The thought was that by demonstrating a heat pipe reactor, a major criticism of the 2010 report could be addressed and be used a foundation to launch a prototypic test.

LANL secured internal R&D funding for this demonstration in early 2012. A meeting was held in Nevada with NASA, LANL and the Nevada National Security Site contractor. Agreements were reached for each organization to fund their part of the demonstration test. The test was set for late summer/early fall of 2012. This early test was named Demonstration Using Flattop Fissions or DUFF. DUFF will be described in more detail later in this chapter.

After the test the Kilopower reactor concept was developed further into the baseline 1 kWe (4 kWt) version for deep space power and a 10 kWe (~40 kWt) version for nuclear electric propulsion and surface power. This concept was documented in early 2013 by LANL and NASA team (Poston et al., 2013).

The birth of KRUSTY test

After the DUFF test was completed in 2012, NASA interest in the Kilopower concept grew rapidly. A white paper called “Why Kilopower” (McClure et al., 2012) was distributed in early 2013 to elicit support for the prototype test.

The Y-12 production facility in Oak Ridge, TN was queried about making the fuel for a Kilopower prototype. Y-12 assured the team that the fuel would be easy to make since it was similar to existing components already built by the facility.

In 2014, the NASA Mars campaign, run out of Johnson Space Flight Center, baselined the Kilopower concept for potential Mars Missions. The Mars campaign need 40 kWt of electricity for the baseline Mars missions. Five 10-kWe reactors (four plus a spare) could perform this mission. A preliminary Mars concept was developed, and requirements for this system were defined in partnership with NASA’s Human Spaceflight Architecture Team (Rucker, 2015).

In early 2014, with support from the Mars campaign, NASA management began to consider funding a prototype of Kilopower. By the summer of 2014, the National Nuclear Security Administration (NNSA) stepped up to be the Department of Energy partner and help perform the experiment. The NNSA managed not only LANL, but the critical experiments at the Nevada National Security Site and the Y-12 production site that would make the fuel. This support became even greater when the Criticality Safety Program in the NNSA agreed to partially fund the project since it could obtain valuable nuclear data (cross-section measurements of BeO) as part of the test. NASA kicked off the Kilopower project in October of 2014 with the goal of completing a nuclear reactor demonstration by the end of 2017. This reactor demonstration was called the Kilowatt Reactor Using Stirling Technology or KRUSTY. KRUSTY will be described in more detail later in this chapter.

The DUFF test

As was described in the 2010 study, a heat pipe cooled reactor had never previously been tested. The Demonstration Using Flattop Fission (DUFF) test was devised as a proof-of-concept experiment for the aforementioned small space reactor.

The test was conducted in September of 2012 and was successful on many levels, but most importantly it produced electricity using nuclear fission, heat pipes, and Stirling engines. DUFF demonstrated the first Stirling engine to be powered with fission energy, the first use of a heat pipe to transport heat from a reactor to a power conversion system, and the first nuclear-powered test of a potential space reactor technology in over 40 years. One of the biggest benefits of the testing was that it provided valuable experimental data. The data demonstrated that the Kilopower concept was viable and the physics well characterized. The data also provided the ability to benchmark criticality and dynamic reactor modeling tools used to design the KRUSTY test. A complete description of the DUFF test is presented by [Poston et al. \(2014\)](#).

DUFF experimental setup

The experiment to model the reactor consists of three main components combined into a single experimental setup. The three components of the experiment are:

- The critical experiment assembly “Flattop”,
- A water-based heat pipe, and
- A Stirling Engine power conversion system.

The three pieces of the experiment were coupled together to form a complete nuclear system that could go critical, develop fission heat, transfer the heat via the heat pipe to the Stirling engine, and the Stirling engine producing electricity.

The Flattop Critical Experiment Assembly was designed to provide benchmark neutronic measurements in a spherical geometry. Flattop includes a spherical core of highly enriched uranium (HEU), a natural uranium reflector, a control system to bring the system critical. A distinguishing feature of Flattop that made the assembly ideal for this experiment was that the HEU spherical core and the natural uranium reflector contain a 1.283 cm (0.505 inch) hole through the reflector and the core. This allows for a 1.270 cm (0.5 inch) heat pipe to be placed into the core with no modification to the existing critical assembly.

The water heat pipe that connected Flattop and the Stirling engine converters utilizes a stainless-steel wall and a sintered-nickel wick and was approximately 114.3 cm (45 inches) in length.

The set up used an electric chiller to provide cold-end temperatures below room temperature, and “off the shelf” Stirling engines that could operate at these temperatures. Two of these engines were used and connected to each other and the heat pipe by means of a copper block. They were specifically designed for, and tested at, low temperatures. The engines were designed to operate at -30°C on the cold end and up to 400°C on the hot end.

The experiment was performed at the Nevada Nuclear Security Site (NNSS) Device Assembly Facility (DAF) which houses the National Criticality Experiments Research Center (NCERC). The complete experimental setup is presented in [Fig. 2](#).

Fig. 2 DUFF, Demonstration using flattop fissions, experimental setup.

DUFF experimental results

The DUFF experiment was performed twice, once on September 13, 2012 and the second time on September 18, 2012. The experiments were very similar except that the first experiment used a rapid ramp up of reactivity, while the second experiment used a slower ramp up. Each is described in detail below.

The timeline of events for the rapid reactivity ramp up experiment are shown graphically in Fig. 3. The test results showed the expected negative temperature feedback behavior of the reactor physics. Fast reactors in this size range are controlled by thermal expansion and subsequent negative reactivity feedback. The simplest representation of this phenomenon is in the fuel. If the fuel heats up then the atoms expand further apart, it is easier for more neutrons to leak out of the fuel and avoid a fission reaction. This leakage results in lower reactivity (lower neutron multiplication), and thus decreases the slope of power production. If the system is operating at steady state, the slope of power will go from zero to negative, thus system power decreases. Therefore, during nominal operation, if more heat is extracted by the power conversion system, then thermal feedback will raise reactor power, or vice-versa. In this manner, the reactor is a load following system component; i.e. the reactor thermal power automatically matches itself to the thermal power removed by the Stirling engines and/or passive heat losses.

The timeline of events for the slow reactivity ramp up experiment are shown graphically in Fig. 4. This test was a repeat of the September 13, 2012 test but with a different rate of reactivity insertion. The test again behaved as expected with reactor power changing to accommodate changes in the power conversion system. This result validated the expected changes given the negative temperature feedback of the reactor.

Summary of the DUFF test

The DUFF experiment demonstrated that a heat-pipe-cooled fast reactor with Stirling Engine power conversion might be a practical reactor concept for space reactor applications. Heat-pipe-cooled reactors have been postulated in the past and tested using separate effects testing (i.e. electrically heated), but this was the first heat pipe reactor using nuclear fission as a heat source. The test demonstrated that a heat pipe cooled fast reactor with Stirling engine power conversion has well characterized physics that can be easily modeled.

Despite its success, DUFF was not a prototypic heat pipe cooled space reactor. Only a small fraction of reactor power was removed by the heat pipe, the rest was passively lost. In addition, the temperature was very low and the heat pipe materials were different. The most important attribute of DUFF was that it showed that nuclear testing could still be done affordably, provided that it is made simple enough. The test laid the groundwork for how to construct a more prototypic Kilopower test that could be completed affordably, and provided credibility to the engineering team and proposed plan. Therefore, the key value of DUFF was that it generated the interest and confidence to pursue a full reactor demonstration, the KRUSTY test.

Fig. 3 DUFF, September 13, Fast reactivity ramp-up test results.

Fig. 4 DUFF, September 18, Slow reactivity ramp-up test results.

The KRUSTY test

After the success of the DUFF test, NASA and NNSA agreed to fund and manage the KRUSTY test or Kilowatt Reactor Using Stirling Technology test. KRUSTY was designed to be a full test of the reactor in a relevant vacuum environment that would demonstrate the key physics of the Kilopower reactor concept. Namely;

- Startup of the reactor with frozen heat pipes;
- Steady state performance of the reactor;
- Load following of the reactor to changes in the power conversion (Stirling engines) draw;
- Fault tolerance to heat pipe failure;
- Verification of temperature change for reactivity changes;
- Ability to withstand a complete loss of active cooling.

The test is described in the next sections. The test is described fully in a series of papers in a special issue of Nuclear Technology (Poston et al., 2020a,b,c; Gibson et al., 2020; Sanchez et al., 2020; Grove et al., 2020).

KRUSTY development plan

The KRUSTY test consisted of three major phases:

1. Electrically heated mechanical prototype testing using a stainless-steel core
2. Electrically heated testing of the system using a depleted uranium core, and
3. Nuclear testing, which was further broken down into three phases.

The major phases of the KRUSTY test are shown in Fig. 5.

NASA's Glenn Research Center (GRC) led the effort to design the test and built the power conversion and heat rejection portions of the system. NASA's Marshall Space Flight Center (MSFC) developed the electrical heat source for the non-nuclear testing and contributed significantly to KRUSTY mechanical design. Los Alamos National Laboratory led the design of the reactor and performed nuclear testing. The Y-12 production facility fabricated the highly enriched uranium (HEU) reactor core. The Nevada Nuclear Security Site Mission Support & Test Services supported nuclear testing at NCERC at the Device Assembly Facility.

KRUSTY thermal prototype development and test

In 2015, the first step to developing a KRUSTY technology demonstration was to validate the form, fit, and function of the power system, and the transfer of heat from the reactor core to the Haynes 230 heat pipes filled with sodium working fluid. Stainless steel was used to prototype the reactor core as an inexpensive option that also has thermal properties somewhat

Fig. 5 KRUSTY development phases.

similar to uranium. An electrical heater was developed at NASA MSFC to heat the core in the central hole that, in the flight configuration, would accommodate a boron carbide poison rod. A vacuum chamber with gas-cooled walls was constructed to accommodate this assembly. Several methods of clamping the heat pipes into grooves cut in the circumference of the core were tested. As a result of this testing, clamping of the heat pipes to the core by encircling the heat pipes with heated stainless-steel rings and allowing them to cool and contract around the assembly provided the best thermal contact between core and heat pipes. This result permitted the project to proceed with the next phase of testing, using non-fissioning depleted uranium (DU) and Stirling engine power conversion.

KRUSTY depleted uranium (DU) test

An electrically heated depleted uranium reactor configuration was tested at GRC during the next phase of the test. This series of testing allowed for evaluation of alternative configurations of the Stirling power conversion interface with heat pipes, and was used to determine the configuration to be used for the nuclear test in Nevada. The testing also served as a dry run of the instrumentation, control, and testing conditions anticipated for the final KRUSTY nuclear test at NCERC.

The DU core alloyed with molybdenum 8% by weight core sections were successfully cast by the Y-12 National Security Complex. While the casting produced core sections that met the specifications for the KRUSTY experiment, the mold geometry and curing furnace temperature profile resulted in small voids in the final casted sections, mostly near the upper surfaces. Changes to the mold geometry and furnace temperature profiles were made, that when implemented for the HEU core section casting, produced excellent results.

The 1-kWe Kilopower reference reactor includes eight Stirling engines for electrical power generation. For the KRUSTY test, two Stirling engines designed for nominally 80 W_e output each were available from the NASA Radioisotope Generator program. For the KRUSTY experiment, it was determined that six nitrogen gas-cooled thermal simulators, controlled to approximate the thermal load of a real Stirling engines, would be substituted for the six remaining Stirling engines at a much lower cost.

Two configuration options of the KRUSTY experiment were assembled and tested in vacuum with the electrically heated DU cores. These configurations differed in the interface between the Stirling engines/simulators and the heat pipes. In the first configuration, the Stirling engines/simulators were grouped in pairs, a traditional configuration for Stirling engines that dynamically balances the linear motions of their pistons to eliminate vibrations in the adjacent spacecraft or planetary surface mounting structure. For this first configuration, the Stirling engine/simulator hot ends were connected to a metal plate that collected heat from two heat pipes. For the second configuration, a second set of heat pipes were built with flared ends that interfaced directly with individual Stirling/simulator acceptor plates. This single engine array configuration requires an electrically operated mass balancer to cancel the vibrations from the unpaired engine. The test of these two configurations allowed the determination of which configuration was simpler and more robust, and which had the lowest weight. The increased efficiency of the second configuration's improved heat pipe/engine interface more than compensated for the mass and power consumptions of the mass balancers, and the single engine array configuration of KRUSTY was selected for the Nevada test at NCERC. This configuration is shown in **Fig. 6**.

Fig. 6 Stirling engines and simulators attached to vacuum chamber bottom.

KRUSTY preparation for nuclear test

The Y-12 National Security Complex cast the KRUSTY HEU core sections during the summer of 2017. The non-nuclear systems were all thoroughly tested and checked out using an electrically heated core simulator earlier in the year, followed by assembly dress rehearsals in a mocked-up NNSS test facility environment located at the GRC aircraft hangar 6. The KRUSTY test hardware was then shipped from GRC and arrived at the NNSS in October 2017. It was inspected before transportation to the Device Assembly Facility (DAF).

KRUSTY nuclear testing

KRUSTY nuclear testing consisted of four phases:

- Reactor Component Critical Testing;
- Cold Critical Testing of the Reactor;
- Warm Critical Testing of the Reactor;
- High-Temperature, Full-Power System Testing.

The test phases were of sufficient length to permit thorough, incremental understanding of the reactivity of the KRUSTY core, and the response of the KRUSTY system to the reactivity changes.

In each of these phases the reactor was made critical on the Comet machine by raising the BeO reflector around the reactor core and inside the shield. This method was used because it takes advantage of the safety qualified lift table on the Comet machine. To have used the control rod in the central hole in the core would have required qualifying a new control mechanism that would have required funding and time not available to the project. **Fig. 7** shows the configuration of the KRUSTY experiment on the Comet platform for various states of reactivity.

The reflector position corresponds to a calculated level of reactivity. During critical experiments, the magnitude of reactivity is determined by the slope of the time-increase in neutron flux (power), and then the reflector is lowered. The measured reactivity is compared to predictions. This process is repeated with increasing levels of reactivity sufficient to confirm the understanding of the experiment performance against predictions.

It is important to note that the difference between moving the BeO radial reflector and a B₄C internal rod (flight) is very small. The raising of the BeO increases reactivity by decreasing neutron leakage, while withdrawing the B₄C rod increases reactivity by decreasing neutron absorption. This difference will cause second order effects on power distribution and feedback, but as far as the neutron population (i.e. power) is concerned, there is very little difference between these two reactivity mechanisms, despite their different geometric locations. This is because KRUSTY is a very good example of a point-kinetic reactor, which occurs when

Fig. 7 KRUSTY assembly on the Comet platform at different stages of reactivity.

the neutron mean-free-path is a significant fraction of the core geometry. In such a system, all regions of the reactor communicate neutronically very well with each other and regional feedbacks effects are negligible (except for how they affect integral reactivity). Therefore, the reactor will respond the same whether reactivity is inserted externally or internally.

Component critical testing

The first-phase testing was the characterization of the reactivity of the KRUSTY reactor components, including the core, reflector, and shielding. The reactor core and shielding were installed onto the top platform of the Comet experiment platform. The reflector was assembled on an elevating lift table, below the core. Numerous component configurations were tested, including changing the material of some components. Iterative tests were performed to determine the reactivity worth of the beryllium oxide reflector and central boron carbide rod. The core first went critical on November 16, 2017. The results of the component critical testing were used to evaluate the analytical model used by LANL to predict reactivity of the KRUSTY experiment. The agreement between the analytical model and the results were outstanding, with only minor variations.

The core was then removed from the platform and installed into the KRUSTY heat pipe and Stirling engine/simulator assembly, and this assembly was installed on top of the Comet platform, to complete the readiness of the experiment for the subsequent critical test phases.

Cold critical testing

With the core, heat pipes, and Stirling engine/simulator assembly integrated, the same process of iterative reactivity increases was repeated. Cold critical testing began on January 12, 2018. This phase of testing continued until the end of February 2018. The results of the cold critical testing were used to again update analytical models and to prepare the system for the warm critical experiments.

Warm critical testing

Warm critical testing began on March 7, 2018. The reflector was stacked BeO with less than 80 cents of total excess reactivity in preparation of the warm critical experiments. The warm critical experiments were used to determine the temperature feedback of the reactor assembly for three progressively hotter experiments. The experiments had the following excess reactivity insertions:

- 15-cent insertion on March 7;
- 30-cent insertion (15-cent followed by small insertions until ~ 30 cents reached) on March 8;
- 60-cent insertion (15-cent followed by small insertions until ~ 60 cents reached) on March 14.

The information obtained from the warm critical runs was used to determine the appropriate reflector configuration (the necessary amount of reactivity excess) for the high-temperature run and was used to validate the accuracy of the analytical models in predicting the behavior of the KRUSTY core during the high-temperature run. The 60-cent insertion test was modeled before the test to predict temperature behavior in the core. This prediction was then compared to actual data after the experiment. The DOE regulator required close agreement between the model and the data prior to proceeding to the high-temperature testing. The peak temperature of the outer surface edge of the core at the axial midplane was used for comparison. The predicted peak temperature was 446°C , the actual was 447°C . The DOE approved the high temperature test approximately 2 days after the end of the 60-cent insertion test. The

Fig. 8 Fully assembled KRUSTY test showing reflector (BeO) in white on platen. Shield block and vacuum chamber above.

BeO reflector was stacked with enough BeO to provide approximately \$2.00 in excess reactivity. **Fig. 8** presents a picture of the KRUSTY experiment on the Comet machine with the lower platen fully loaded with BeO.

28-Hour high-temperature, full-power test

The final full-power (~ 4 kWt), core temperature at 800°C , 28-h experiment was begun on March 20 and ended on March 21, 2018. The final phase of testing consisted of a simulated space mission profile for a Kilopower system. Start-up of the fission power system was accomplished by increasing reactivity gradually over $1\frac{1}{2}$ h until the core reached 800°C ; temperature was measured by 18 thermocouples placed on the outer edge of the fuel. The Stirling engines were started at approximately 1.2 h. Steady state full-power operation was held for approximately $5\frac{1}{2}$ h to validate normal operation. Over the remaining 21 h a set of transient experiments were performed on the core to demonstrate the self-regulating characteristics of the Kilopower reactor. These transients included the following:

- Demonstrating load following characteristics by increasing the stroke on the Stirling engines to increase power draw on the reactor core. The stroke was then decreased to lower the power draw on the reactor core.
- Simulating the failure of one and two Stirling engines.
- Adjusting the reactivity to demonstrate the core temperature response.
- The turning off of all active heat removal by the power conversion system.

Fig. 9 shows a condensed version of the results over the entire 28 h of the nuclear system test. The time scale on **Fig. 9** and all subsequent plots is in hours, relative to planned test start time “T-0” of 10 am Pacific Daylight Time (PDT) reprinted from [Poston et al. \(2020c\)](#). The figure displays three types of measurements. The majority of the colored curves plotted depict fuel thermocouple data. The figure contains a red line that represents fission power, although the actual measurement is a current (in amperes (amps)) reading from a neutron detector, and fission power was later normalized to amps. A dashed black line on the figure depicts the relative platen (lift table) position. KRUSTY’s reactivity is changed by axial movement of the BeO radial reflector on the COMET platen. The value displayed was normalized so it could be cleanly co-plotted along with other variables on a common scale.

Startup and steady-state operation

At $T = 0.63$ the core temperature reached 500°C and the heat pipes began to “operate” (i.e. at temperatures less than 500°C there was not enough sodium vaporization within the heat pipes to transfer significant power). After the heat pipes “turned on,” the core gained access to the thermal inertia outside of the core. At $T = 0.67$, the core temperatures started to significantly diverge. The temperature near the bottom of the core resumed a heat-up rate close the adiabatic value ($\sim 30^\circ\text{C}/\text{min}$), while the temperatures

Fig. 9 Power and temperature data from the 28-h KRUSTY nuclear system test.

near the top were cooled very well. This is a clear indication that the heat pipe was struggling to remove power from the bottom of the core. At $T = 0.92$, after the condenser temperature had finally caught up to the rest of the heat pipes, the reactor power starts to uniformly heat up the core and entire heat pipe, and move the heat pipe away from the temperature limited regime. At $T = 1.14$ the two Stirling convertors were turned on as planned, when the temperature of the hot end of the Stirling engines reached greater than 650°C , which is the nominal operating point of the convertors. At $T = 1.7$ the system had reached quasi-steady state; i.e. a state where the core and Stirlings were in sync with each other, and only external or second order factors could significantly alter system power and temperature.

Load following transients

The cornerstone of the KRUSTY transient testing was to assess the thermal load-following capability of the Kilopower reactors. At $T = 8.0$ h the power draw from the Stirlings was reduced. The reduction in heat removal caused a rise in average core temperature, thus a decrease in reactivity (primarily via thermal expansion causing more neutron leakage) and thus a drop in power. The gradual drop in power subsequently caused core temperature to fall back toward the reactor “thermostat” set-point of $\sim 800^{\circ}\text{C}$.

At $T = 10.02$ another positive step change in power draw was initiated. The Stirling engine simulator flow rates were increased to approximately double their power draw. The increase in simulator flow caused the fission power to change from 2.75 to 4.05 kW, a rise of 1.3 kW. As with all of the load-following transients, the fuel temperatures responded very quickly to the increased power removal; the increased heat removal inside the simulator was fully evidenced by a drop in the fuel temperature.

Fault tolerant transients

One of the most attractive features of Kilopower systems is reliability, including the ability to avoid single-point failures and in many cases tolerate numerous failures. The “fault tolerance” transients were conducted to verify the ability of KRUSTY to deliver nominal power in the case of failed Stirling modules. A Stirling module (also referred to as a string) includes the heat pipe, the Stirling, the heat rejection, and the interfaces that connect them; these components are in series, so a failure of any of them fails the string. In KRUSTY, the flow through the simulators was cut-off to fail the string. The heat is redistributed to the other “strings” such that the reactor continues to produce full power. Fig. 9 show the fault-tolerance transients occurring from $T = 12$ to $T = 14$.

Reactivity control transients

The “reactivity control” transients were conducted to measure the clean reactor response to system reactivity changes. Fig. 9 show the response to the reactivity control transients, which occurred from $T = 16$ to $T = 20$. The platen containing the BeO reflector was gradually raised to its highest position during the testing. This subsequently took the KRUSTY reactor to

its highest temperature of 840 °C (840 °C was the measured edge temperature, the internal temperature is estimated to reach ~880 °C). The rate of insertion was kept slow enough to prevent a very high-power spike, with the goal of peaking at 5 kW thermal power output.

Loss of heat removal

The final transients were conducted to determine the response of KRUSTY to a complete loss of active heat removal and abrupt restart of the convertors and simulators. Fig. 9 plots these transients, which occurred from $T = 20$ to $T = 28$, ending with the reactor scram. The most important of these tests was the removal of active cooling. During this transient, the core temperature quickly increased, decreasing reactivity, causing the power to drop shortly thereafter. During the transient, the average core temperature reading rose about 16 °C showing overall safety of the reactor design. These experiments show that reactor could not have a core melt accident caused by total failure of the heat removal system (i.e. the Stirling convertors).

Final assessment of the KRUSTY experiment

The KRUSTY experiment demonstrated that the Kilopower reactor concept would perform as designed. The desired performance parameters versus the outcome of the experiment are shown in Table 1.

Kilopower applications overview

Reliable, long-life power systems are among the basic requirements of any space exploration mission. NASA has relied upon plutonium-based radioisotope power systems (RPS) (Bennett, 2021) for decades for deep space missions like Pioneer, Voyager, Galileo, and Cassini, where solar power was not a feasible option. RPS systems provide reliable and lightweight power for missions in the 100-W_e to 1-kW_e range. Kilopower was developed to address NASA's needs in the 1- to 10-kW_e range, potentially up to ~30-kW_e with the same technology. For science missions to the outer planets, Kilopower could enable future flagship science missions and exploration precursor missions that may not otherwise be possible. For human missions, Kilopower could provide surface power system modularity, mobility, and reliability for Lunar and Mars surface missions.

Example Kilopower missions

Kilopower was designed for numerous missions both for planetary surface power and for deep space missions. Examples of both types of missions are presented below. The detail presented varies by mission. The analysis for these missions was done by different NASA centers with varying objectives. As such, consistent mission data was not available.

Example planetary surface missions

Mars

The first mission discussed for Kilopower was as a power supply for human missions to Mars. The Human Spaceflight Architecture team has assumed four 10-kW_e power systems for the 40-kW_e first human Mars surface mission requirement, with a possible fifth unit for added reliability.

Moon

The other planetary surface mission that has been proposed for Kilopower is a technology demonstration mission for the lunar surface. A 10-kW_e reactor has been proposed for deployment in the mid-2020s. The reactor would be part of a lander demonstration. Potential missions could be as either a power source for rovers or a power source for an In-Situ Resource Utilization (ISRU) demonstration unit.

Table 1 KRUSTY experiment outcomes.

<i>Event scenario</i>	<i>Metric</i>	<i>Experiment</i>	<i>Status</i>
Reactor startup	<3 h to 800 °C	1.5 h to 800 °C	Exceeds
Steady state performance	4 kWt at 800 °C	>4 kWt at >800 °C	Exceeds
Total loss of active cooling	<50 °C transient	<15 °C transient	Exceeds
Converter efficiency	>25%	>30%	Exceeds
Converter operation	Start, stop, hold, restart	Start, stop, hold, restart	Meets
System electric power turndown ratio (operational range)	>2:1 (half power)	>16:1	Exceeds

Example deep space missions

The National Academy of Sciences 2013–22 Decadal Survey (National Research Council, 2011) identified many RPS-powered mission concepts that could be performed using a 1-kWe or 10-kWe reactor. A reactor-powered Nuclear Electric Propulsion (NEP) system for these missions would support an increased science payload mass, increased communications rate, and shorter flight times. With a lesser increase of science payload mass, an NEP system could also support a greater than 40-year mission life-time. A 10-kWe NEP system can provide the power for multi-year outer solar system robotic missions, such as a Neptune+Triton Orbiter, Chiron Orbiter, Titan+Enceladus Orbiter, Pluto Orbiter and Kuiper Belt Object Orbiter (Casani, 2019).

Conclusion

Kilopower is designed to provide from 1 to 30 kWe with a simple and robust technology, and can ultimately evolve up to 5 MWe with a few manageable stepwise technology changes. The Kilopower technology development and demonstration project has stepped through a build-and-test sequence of phases that completed the demonstration of a flight-like system operated at prototypic conditions in a relevant environment (Technology Readiness Level (TRL) 5) for space science and human exploration power needs. The innovations of monolithic reactor fuel and heat pipe heat transfer have been applied and tested through all challenges. The nuclear steady-state and transient test of this space reactor is the first such experiment performed in the United States since the 1960s. This accomplishment establishes the readiness of nuclear-tested fission power system technology for affordable, lightweight application to human and robotic exploration wherever it is needed.

Introduction

Nuclear Thermal Propulsion (NTP) describes a class of technologies that use nuclear power to thermally heat a rocket propellant. Traditional rockets utilize a chemical reaction to heat the rocket propellant, whereas NTP uses the heat from nuclear reactions. An NTP concept is usually referred to as a Nuclear Thermal Rocket (NTR), although both terms are often used interchangeably. In general, and in this encyclopedia, the term NTP is associated with fission reactors that heat a hydrogen propellant. Fusion, anti-matter, pulsed-nuclear, or other nuclear powered concepts might still be technically labeled as NTP, but they are usually referred to under the category of advanced nuclear propulsion ([Howe, 2021](#)). Advanced concepts may offer performance advantages (on paper), but NTP has the distinct advantage of having established nuclear physics and to some extent proven technology.

Nuclear thermal rockets have been dreamed of since the discovery of fission in 1938. The dream of NTP came close to reality during the Rover and NERVA programs, which occurred in the US from 1955 to 1973. Substantial progress was made as 20 different reactors were designed, built, and tested over that period; unfortunately, none of them reached the flight-development stage, and no NTP reactors have been built since then. Several smaller scale NTP programs in the US and Russia have been conducted over the past 50 years. A detailed look at the history of NTP is presented in the next chapter in this encyclopedia ([Graham, 2021](#)).

Benefits of NTP

The benefit of NTP is rooted in the rocket equation.

$$\Delta v = v_e * \ln \left(\frac{m_{initial}}{m_{final}} \right) = I_{sp} * g_0 * \ln \left(\frac{m_{wet}}{m_{dry}} \right)$$

Specific impulse (I_{sp}) is a measure of how much thrust occurs per mass of propellant (with a unit of seconds), which is directly proportional to the rocket propellant exit velocity (v_e). Delta- v (Δv) is a measure of useful acceleration. Therefore, first order rocket performance is a linear function of I_{sp} ; i.e., double the I_{sp} = double the Δv . However, the benefit of higher I_{sp} can be much greater depending on the proposed mission; the more ambitious the mission (higher delta- v) the greater the benefit of higher I_{sp} . This is because of the logarithmic mass ratio in the rocket equation of initial (wet) mass vs. final (dry) mass: wet mass (m_{wet}) is mass of spacecraft plus propellant, dry mass (m_{dry}) is the spacecraft without propellant. For ambitious missions, a lower I_{sp} will require exponentially more propellant (wet mass) simply to push the additional propellant needed, to the point where either the launched mass is nearly all propellant, or the mission cannot be performed at all. In these cases, a substantial increase in I_{sp} can be provide more than a factor of two benefit.

As a heated gas is exhausted through a nozzle, the I_{sp} (exit velocity) is a function of the gas temperature, molecular weight, and ratio of specific heats ((specific heat at constant pressure)/(specific heat at constant volume) usually referred to as gamma). The ratio

of specific heats is relatively similar for all gasses, so in general I_{sp} increases with the square root of temperature and decreases with the square-root of molecular weight. Hydrogen (H_2) is the only gas with a molecular weight low enough to provide performance better than a traditional chemical rocket; thus it is the only propellant worth considering for NTP (unless perhaps a planet/moon has a large quantity of available Helium). The I_{sp} vs. temperature for H_2 propellant is shown in Fig. 1.

The I_{sp} of a hydrogen-oxygen chemical rocket is ~ 450 s, so Fig. 1 can be used to show that a H_2 chamber temperature (mixed-mean reactor outlet temperature) needs to be ~ 800 K to equal the best chemical rocket. Since NTP is an unproven technology then it would at least have to achieve at least 500 s to even be worth a second look. However, an NTR will likely have a much heavier dry mass than a chemical rocket, so the I_{sp} of an NTR may need to be > 600 s to be useful, and perhaps > 700 s to be cost effective on a per mission basis (considering that at NTP unit will likely cost more than a chemical unit). Then, given the high cost/difficulty of development and testing, a target of > 800 s is generally the low end of where NTP is considered worth pursuing. Of course, these targets are all generalizations, and could change by up to 100 s either direction depending on the intended application, the development cost, and the unit cost.

The highest gas outlet temperature of any fuel element during the Rover/NERVA program was 2550 K (Koenig, 1986), which would imply an I_{sp} of 850 s; although this was at rather low power density and was not an integrated “rocket” test. The XE’ test was closest to a potential flight-prototypic rocket test of any Rover/NERVA test, and had an fuel exit temperature of > 2400 K; this would imply an I_{sp} of 810 s, but the actual overall rated I_{sp} was only 710 s (Finseth, 1991). In order to keep things simple, they did not attempt to implement some design features that would have improved system I_{sp} closer to 800 s.

Most NTP studies since the Rover/NERVA program have targeted an I_{sp} range between 850 and 950 s, because there is almost no experience with fuel materials that can survive > 3000 K temperatures (although there are several proposed fuels that could). Plus, engineering realities dictate that the gas outlet temperature of at least 100–200 K below the maximum fuel temperature. Highly advanced concepts have been proposed with liquid or gas fuel (with corresponding cooled walls) to increase I_{sp} well above 1000 s. Gas or plasma core rockets have been theorized with I_{sp} as high as 3000 s, but these concepts are a long way from reality. For the remainder of this article, the discussion will generally pertain to an NTR with an I_{sp} of ~ 900 s, which provides a factor of two improvement over hydrogen-oxygen chemical propulsion.

Human Mars missions are the kind of ambitious missions for which NTP can be very attractive. For one class of mission, conjunction class (where at launch, Mars is on opposite side of sun from Earth), the primary benefit of NTP is a reduced number of earth-to-orbit launches required to ultimately get the payload to Mars. Given the large payload of a human Mars mission, up to a factor of two fewer launches could provide a great cost savings. Also, less in-orbit assembly and fueling could make the mission architecture simpler and thus even less expensive. The net benefit of NTP for a conjunction class mission depends greatly on the cost of heavy-payload earth-to-orbit launches. Currently (in 2020) there is a major effort underway to reduce heavy-lift launch costs.

Fig. 1 Rocket specific impulse versus chamber ($\sim$ reactor outlet) temperature.

SpaceX has made the most progress to date, and if SpaceX, Blue Origin, NASA, etc. succeed in substantially reducing heavy-lift launch costs, then the value of NTP for conjunction class missions will be significantly diminished. If that occurs, then NTP might only be worthwhile if a human-rated (i.e., very high reliability) system can be developed at relatively low cost (perhaps for billions of dollars as opposed to the perceived cost of 10s of billions). Fortunately, NASA has had a significant program underway since 2011 to determine the “affordability” of NTP, and it’s ramping up to an even larger effort in 2020. Thus, by the mid-2020s we should have a good answer concerning both issues: the cost of heavy-lift and the feasibility of affordable NTP.

The other class of human Mars mission proposed for NTP is an opposition-class mission (where at launch, Mars is on same side of sun from Earth). Opposition-class mission are shorter; the time spend on Mars is only ~ 1 month vs. ~ 18 months for a conjunction class mission. This shorter time may be attractive for early exploration missions to minimize time at risk for the astronauts, at the expense of potential exploration advantages of a longer stay. However, for an opposition-class mission the return trip from Mars is much more difficult and of longer duration. For chemical rockets, the time in space is almost a year longer, which eliminates most of the time advantage of the opposition-class mission (depending on the astronaut risk in space and/or on the surface). NTP however, has the potential for a much quicker return trip, which is probably the biggest advantage of NTP for exploration in the near future.

For an opposition class mission, the value of NTP depends on how much astronaut risk is reduced by shorter trip times. Risks to astronauts can generally be binned into four areas: zero-gravity risks, radiation risks, away-from-home risks, and acute-mission risks (caused by system failures). Zero-gravity effects are becoming well known. The most pronounced effects of zero-g are loss of muscle and bone mass, which can be partially mitigated by exercise with specialized equipment, and consequences of the redistribution of fluids in the body (e.g., vision impairment, cardiovascular issues, etc.), which can be partially managed by constrictive clothing. There are many other potential zero-g issues that could provide significant health consequences, which will learn about as human beings spend more and more time in space. Fortunately, astronauts have already accumulated substantial time in zero-g (technically micro-gravity, but essentially the same) over the past decades, which has not only shed light on the risks, but in many cases has led to mitigations of to zero-g risks. To date, no health issues have been identified that would preclude a human mission to mars, or effect a crew in a way that would likely jeopardize a mission. The biggest issue is to allow astronauts time to recover and adapt, so they can perform their duties once they reach Mars.

The most emphasized risk for a human Mars mission usually radiation, even though there is no compelling evidence that dose received from the astronauts would create significant health issues. It is expected that a Mars astronaut would receive on the order of 1 Sv during a Mars mission (unless a significant solar storm occurs and an adequate storm shelter has not been provided). This dose rate is well below the threshold of any acute/deterministic radiation effects; although astronauts have developed cataracts at a higher rate than the general public, which could be due to radiation, zero-g, or a combination of factors. The only other potential risk from radiation is genetic damages that might lead to cancer. The highly conservative (and greatly disputed) linear-no-threshold model indicates that 1 Sv of accumulated dose creates a $\sim 10\%$ chance of developing cancer. Even if true, this has almost no chance of occurring during the mission (5–15 year latency for leukemia and 10–60 year latency for solid tumors), and most likely much later in the astronaut’s life—if they are lucky enough to survive the mission and celebrate life as a hero to old age. More-so, cancer is becoming less and less fatal (33% survival in 1975, 25% survival in 2010, etc.), and by the time we eventually send an astronaut to Mars mortality rates may be very low. In any case, these radiation risks are insignificant compared to the risks taken by any significant explorer or pioneer, including NASA’s previous test pilots and astronauts.

Away-from-home risks, or more properly labeled away-from-civilization risks, have existed for every exploration campaign in human history. Once the astronauts leave earth they no longer have access to “standard” medical care; therefore, a condition that might be easily treatable on Earth may end up fatal on a spacecraft or on the Mars surface. There is also concern about the psychological effects of years of isolation in close quarters with a handful of crewmates. Several experiments have been conducted to study human behavior under simulated Mars mission conditions (Binsted et al., 2010); although there is no way to simulate the certainty of having zero chance to set foot on Earth for months/years. The reduced trip time offered by NTP would definitely be beneficial in this regard, although there is no clear evidence that any of the above issues will provide a major risk to a human Mars mission.

All of the above risks (zero-g, radiation, and away-from-home) appear to be very small when compared to acute-mission risks that can be caused by system failures. The “simple” act of launching into Earth orbit on a relatively new heavy-launch vehicle will likely be more risky than the combined effect of all of the above risks. A highly utilized spacecraft, the Space Shuttle, performing a relatively simple mission killed $> 1\%$ of astronauts. On a Mission to Mars astronauts can die acutely via: launch, Mars trajectory burns, Mars capture, landing, ascent, docking, Earth-return burns, Earth arrival and landing (and perhaps a Venus flyby or Mars aero-capture). That’s at least eight distinct risk points that each would be extremely hard to get below a 1% failure rate, and realistically may average 2% each (and maybe even higher if a very new technology is used like NTP). Then at any time during the mission there are a slew of risks, most notably loss of power supply, life support, vessel/space suit integrity, fire, etc. Not to mention risks due to human error by crew members or ground personnel. The sum of risks for a human Mars mission are daunting, but there will surely be no shortage of volunteers willing to take that risk for the benefit of us all, let alone the chance at fame and fortune.

The increased safety of a shorter trip time has to be weighed against all risks, and the cost of developing a useful NTP system. This comparison (for an opposition class mission) is less straightforward than it is for conjunction class missions, where the cost of developing NTP can be weighed against the increased launches and space integration required for a chemical mission. Noting that the cost of developing an NTR is a very strong function of requirements, most notably I_{sp} and thrust-to-weight, and potential policy issues concerning highly-enriched uranium and/or launch accident safety.

Another way that NTP can be used to increase safety is by providing increased ability for mission abort. For any given mission, a higher I_{sp} reduces the mass penalty to carry propellant margin to allow unplanned burns to get home quickly if an emergency occurs. Some NTP missions may even provide enhanced mission abort options with a minimal mass penalty (Joyner, 2017). Another potential advantage is that higher I_{sp} can enable potentially safer higher delta-V missions to Mars, e.g., by avoiding gravity flybys or aero-capture. This would increase propellant mass versus the “nominal” mission, but higher delta-v option might not even be possible for a chemical mission. In general, these benefits would need to be traded against the mass benefit for a conjunction-class mission or the nominal return travel time for an opposition class mission. The value of this flexibility is highly dependent on mission trajectories; e.g., some missions could more easily benefit from a mission abort capability than others.

The benefits of NTP also have to be weighed against other technologies than chemical propulsion; this includes the advanced technologies mentioned earlier, but most notably electric propulsion. Electric propulsion allows much higher I_{sp} than NTP, perhaps up to 10,000 s as compared to 1000 s. Electric propulsion is used regularly in space, but is generally very low thrust, so at the moment not very attractive to human missions. Solar electric propulsion is promising near the Earth, but becomes less and less attractive further out towards Mars and beyond. For a human Mars mission, Nuclear Electric Propulsion (NEP) is the other potential candidate besides NTP and chemical propulsion. A discussion of Nuclear Electric Propulsion is provided in another chapter in this encyclopedia (Morrison, 2021).

Ultimately, if NTP can be successfully developed, there are many other potential benefits beyond a human Mars mission. In general, NTP will allow missions that are twice as ambitious as chemical propulsion, i.e., twice the delta-v. Higher performance systems could potentially carry humans to the moons of Jupiter, and perhaps beyond. Low mass, low thrust system could benefit deep space science and maneuverability in sis-lunar space. For grand-scale missions, NTP could be used in tandem with higher I_{sp} nuclear electric propulsion (NEP) system, to provide high thrust when needed and/or escape gravity wells. Bimodal NTP systems could offer the benefit of providing both thrust and electric power. The potential benefits on NTP are great, but like all engineered systems, the desire for higher performance (higher I_{sp} , lower mass, greater flexibility) comes at the cost of more difficult development and technical risk.

Challenges of NTP

The benefits of NTP are impressive, so ultimately the attractiveness of NTP depends on the cost and effort of developing and utilizing a reliable system. In some ways, NTP has certain development advantages: e.g., short reactor lifetime and minimal radiological consequences of an operational failure in space. In other ways, nuclear thermal rockets are far more challenging than any other reactor applications: e.g., high temperature, high power density, and the use of a volatile coolant (H_2). Overall, the technical challenges are daunting, but the various successes of the Rover/NERVA program provide some confidence that success could be achieved; although this may depend greatly on how similar any specific concept might look to a Rover/NERVA system, and whether we have the will to pursue and complete a program on the vast scale of Rover/NERVA.

Technology challenges

Reactor fuel

The nuclear fuel for an NTR is a significant technology challenge. The fuel temperature required for a “useful” NTR is probably 2600–3000 K, which is significantly higher than any other reactor operated in the past 50 years (LWR power plant fuel has a peak internal temperature of ~ 2000 K, and the fuel structure/cladding operates at < 1000 K). In addition, the fuel power density required for acceptable rocket performance is generally 5000–10,000 W/cc, which is an order of magnitude higher than other power reactors (LWRs are on the range of 100 W/cc, advanced test reactors up to ~ 500 W/cc). The fuel, and associated coatings or internal structures, must also be resistant to erosion and corrosion to hydrogen flow at high velocities and high temperatures.

The raw fuel material itself is not necessarily the challenge, as there are several options that have melting points > 3000 K (UO_2 , UN, UC, and many more). The challenge is being able to fabricate the fuel (and internal structure) in a way that not only accommodates heat removal, but can survive extreme combination of stress, temperature and potentially vibration. The Rover program made a lot of progress in developing a carbon-based NTR fuel, the Pewee reactor fuel operated at a peak temperature of 2750 K (Finseth, 1991), but after 20 nuclear reactor tests there were still issues with erosion, corrosion and cracking. Many present day concepts propose using different fuels, with less heritage but perhaps better capability. Once a fuel is produced, then environmental testing will have to be performed to see if it can survive the proposed NTR conditions. A discussion of historical and proposed fuel types can be found in the following chapters in this encyclopedia Graham (2020) and Poston (2021).

Reactor structure

Reactor structure for an NTR is unique when compared to any other class of reactor. The biggest challenge is that during operation the reactor is very hot on one end (likely 2500–3000 K) and very cold on the other (perhaps 200 K), and there are other states (during startup and shutdown) where the entire reactor might be very hot or very cold. The various possible thermal states create a complex combination of expansion stresses, at temperatures where material properties might be structurally challenged (e.g., lack of strength at very high temperature or lack of ductility at very low temperatures). Hydrogen also has the potential to embrittle the structural materials, in addition cause potential corrosion/erosion.

In addition to steady-state challenges, the structure must also be able to survive the potential thermal shock caused by the injection of extremely cold coolant into a warm reactor, and transient stresses caused by rapid heat up. The structure must also be able to survive launch loads/vibrations of a heavy-lift rocket, and there may be structural requirements to prevent criticality that could be caused by an accidental impact. Finally, the structure must allow for the routing and distribution of high-pressure hydrogen flow to various flow paths throughout the system (in some cases two or three different flow streams in different directions), and all of the associated stresses.

The Rover/NERVA tests had numerous structural failures during early testing. Koenig (1986) lists 16 “significant structural anomalies” that occurred over the 6 design iterations of the NERVA NRX test series, including cracking, flaring, rubbing, breaking of various components. They were able to learn and resolve issues with continued design and testing, but any new NTR concept may likely require several ground test iterations as well.

Heat transfer and power balance

One of the design goals of an NTR is to warm the H_2 propellant as much as possible, i.e., maximize the mixed-mean outlet temperature. In a fission reactor, some regions of the fuel produce higher power than others—the ratio of peak power to average power is referred to as a peaking factor. A typical NTR heats the H_2 coolant by ~ 2500 K from core inlet to outlet; thus, if the nominal flow rate was used to cool a fuel region with 10% more power (i.e., a peaking factor of 1.10), it would have an outlet temperature 250 K higher than the average flow. To prevent this from happening each flow channel (or at a minimum each fuel assembly) must be orificed to match the flow rate to the power. This can be mitigated at the nominal design conditions (depending on the uncertainty in power deposition and pressure drop), but this can be complicated and diminish performance in cases where reactor peaking factors change with burn-time and control element position.

Nuclear power deposition also occurs outside of the fuel, as neutron and photons interact with other materials. Given the high power of most NTR concepts (> 100 MW), other reactor components and regions must also be actively cooled by the H_2 . Some of the regions that require adequate cooling are the neutron reflector, shield, vessel, and nozzle. In some cases too much cooling could be as detrimental as too little cooling, due to the need to balance reactivity feedback (Deviation from the state of a critical core—a core that sustains a fission chain reaction.), as well as provide the desired coolant temperature to the turbopump. Therefore, the power deposition and flow balance to all components must be well matched and have minimal uncertainty.

An NTR will generally operate as close to material limits as possible to maximize I_{sp} . It is important that heat transfer paths are robust and predictable, because small changes in thermal resistance can cause big changes in temperature gradient (due to the extremely high power density). If dissimilar materials or coatings are used, it is important to ensure that their interfaces will maintain the expected thermal resistance throughout all operating regimes. The effect of system strain/deformation on thermal resistance and heat transfer must also be considered, for all possible thermal/mechanical states of the system.

The most difficult heat transfer/balance challenges occur if the reactor core contains sub-cooled regions (i.e., regions that are cooled to be at lower temperature than the primary fuel and coolant), which might contain structure and/or moderator. In these cases an insulating material must be used to prevent heat from “leaking” from the fuel to the colder nearby region. Heat leakage not only decreases I_{sp} , but also requires more coolant flow through the sub-cooled region (which increases pressure drop and/or requires more flow area). The insulating material must be effective at very high temperature, and also meet neutronic requirements, by allowing a compact geometry and not absorbing too many neutrons. The Rover/NERVA program spent considerable time developing high temperature insulation, with fairly good success, but they also acknowledged that it would be very hard to predict performance in a system application without actually testing it within the system (Wagner, 1992). One of the biggest contributors to uncertainty they identified was hydrogen infiltration into the insulation, which could change conductance by up to an order of magnitude. Unfortunately, it is extremely hard to guarantee that H_2 would be kept out of a region at $\gg 2000$ K, and also hard to ensure that it would be fully saturated with H_2 (while also precluding convection); therefore, there will be very large uncertainty in insulation performance simply based on the unknown effect of H_2 on thermal conductance alone. It is important that the thermal performance of the insulator is well-understood, because the thermal resistance has a major effect on balancing the flow, temperature, and reactivity of the sub-cooled region (as mentioned previously, too little insulation will overheat the region and too much insulation will starve the pump from power).

Decay power removal creates another potential problem involving power balance and the use of a subcooled moderator. A concept with a moderator must keep that moderator cool after shutdown, assuming that the NTR is planned to be used for more than one burn. This creates two issues. First, the reactor must be actively cooled for a longer period on time; i.e., until the decay power decreases enough to match the lower passive heat rejection that occurs at the lower core temperature. Second, and more importantly, the cooling efficiency (J/kg) of the post-burn cooling flow will be substantially lower, because it will have a lower outlet temperature. Any NTP concept will require a certain amount of “wasted” propellant to remove decay power—not totally wasted, but the I_{sp} will be lower and the thrust profile will be unpredictable and sporadic. The problem created by an internal moderator (or any low temperature core region) is the existence of the thermal path from the fuel through the insulation. At nominal high temperature, the flow through the insulation might be 5–10% of the nominal power. At decay power levels ($\sim 1\%$), the fuel will quickly lose its high temperature via heat transfer through the insulation, and settle at a temperature slightly above the moderator/block/tie-tube temperature; thus the outlet coolant can’t be heated to a temperature significantly higher than the moderator. In a typical mission scenario, the total removed Joules of decay energy might be $\sim 2\%$ of the Joules of the entire active burn. If the use of a moderator requires the core temperature to be four times lower for decay mode versus nominal mode, then the amount of decay-mode propellant (“wasted”) would be 8% ($4 \times 2\%$) of the nominal flow; severely reducing

effective I_{sp} . An unmoderated NTR has the benefit of allowing the core to remain at or near the nominal max operating temperature. Although in that case, the issue might be keeping the vessel or structure cool, which could also decrease the efficiency of the decay power flow (but likely by a much smaller amount).

Individually, each of the heat transfer issues are difficult engineering challenges, occurring at extreme temperatures and power densities by most standards. What makes them even more difficult is the combination of uncertainties and reactivity feedback effects, and the difficulty of testing heat transfer without a full integrated test (because nuclear power is the only way to produce high enough power deposition in the fuel and other components).

Reactor instrumentation and control

Instrumentation and control is a challenge for almost any nuclear reactor, and NTP adds another layer of complexity and uncertainty. Establishing the reliability and accuracy of diagnostics in nuclear reactors is difficult, but 50+ years of experience has led to adequate solutions for terrestrial reactors (often via lots of redundancy). An NTR will have radiation fluxes and temperatures that far exceed any existing reactor, and thus there will be uncertainty regarding the readings of any instrumentation. In-core temperature measurements may not be possible at all, which would present a major problem for any system that has complex reactivity feedback and sub-cooled regions (i.e., more than one significant temperature reactivity feedback mechanism). The desire for low-mass may also limit the number of diagnostic instruments, possibly preventing diverse and redundant readings. In addition, the diagnostics must operate in the vacuum and extreme temperature of space, survive launch vibrations, and operate during the vibrations created when the NTR is thrusting.

Most NTRs propose to use rotating control drums to change reactivity, where one side of the drum contains neutron reflector and the other contains neutron absorber. The high power deposition in the drums/reflector combined with very cold coolant has the potential to create warping that might cause the drums to bind. Thrust vibrations may also effect clearance and rotation, as well as the thermal cycles between high temperature operation and the extreme cold of space between restarts. The rotation mechanisms must be robust to launch loads and prevent inadvertent rotation during potential accidents, and the motors must survive the temperature and radiation environments. Also, in some NTR concepts, active, rapid response control requires high speed drum movements.

The final challenge is developing a system to properly and reliably command the control mechanisms based on the diagnostic information. The biggest difficulty might be deciding which instruments to “believe,” because experience shows that all readings are not normally in agreement (some signals may be faulty while other signals experience drift). Usually when a reactor starts up, there is a long period of preliminary operations to flush out the system and learn which signals are bogus and what the remaining signals are actually inferring. An NTR will not have much opportunity, if any, to do this, because hydrogen must be flowing to diagnose the system and there is a strong desire not to “waste” propellant before going to a fully operational state. Then, after the input signals are processed, a computer must decide what actions to take and convey signals to the drum motors. Adequate shielding will need to be provided to the computer (likely more than 1 computer for redundancy) to avoid a single-event upsets caused by radiation.

Turbopump power and control

A high-thrust, high- I_{sp} NTR requires high volumetric flow rates and high pressure drops, because flow area is limited by nuclear criticality and high velocity is needed to enhance coolant heat transfer. This combination of high flow and pressure drop requires considerable pumping power. A turbopump is generally the only practical pumping option, except for extremely low-thrust systems where an electric pump, chemically driven pump, tank pressure, or other options might work. The pump hardware should not present a major technology challenge, because hydrogen turbopumps have been successfully developed and used for decades (including the space shuttle main engine). Radiation damage or power deposition could be an issue for seals and bearings, but this is not expected to be a major problem.

Power for the turbopump (to heat the turbine feed propellant) must come from the reactor: directly or indirectly, except for startup where an external power source could be provided or tank pressure can be sufficient. Some of the power can be provided by the regenerative cooling of the nozzle, plenum wall, reflector, shield, etc. For a very low pressure drop design this regenerative power might be adequate to power the turbopump (depending on the flow rate and the flow resistance though other components), but criticality requirements usually drive NTR designs to minimize flow area, and the resulting pressure drop is high enough to require substantial pumping power. The vast majority of NTR concepts require an additional source of heat to power the pump turbine.

During the NERVA program, there was only one system test that used a turbopump, the XE' test (Aerojet, 1969), where a hot-bleed cycle was used to power the pump. A hot-bleed cycle removes hot H_2 from the nozzle region to provide power for the turbine, and it is mixed with cold flow to make the turbine inlet temperature manageable. The hot bleed cycle was used for XE' because it was deemed easier than a topping cycle (where the turbine feed flow passes through separate channels in the core); although, pulling $> 2000\text{ K } H_2$ from a flow stream is certainly not “easy.” The major drawback of the hot-bleed cycle, combined with an open-cycle turbopump (where the turbine exhaust is ejected instead of recycled), is a reduction in I_{sp} . NERVA documentation states that they settled for the simpler, lower performance to complete XE', and would pursue a closed topping cycle in the future. A topping cycle is difficult because special sub-cooled flow paths must be integrated into the reactor and plenum design. These cold flow paths must be maintained next to extremely hot components (hard to insulate, potential for thermal stresses), they add regions of relatively high-density H_2 in the core (complicates reactivity), and plumbing must be integrated to provide for the inlet/outlet of this flow (difficult to engineer and never demonstrated).

Perhaps the biggest challenge for an NTR turbopump will be control. Most standard turbopumps, from cars to rockets, have a relatively direct and predictable response to increased flow—increased flow causes more combustion and a proportional increase in power that returns to the turbine. A subsequent increase in passive losses and reduced combustion efficiency dampen the system to a stable settling point. The dynamics that drive an NTR turbopump will be totally different, and depend greatly on the reactor design. The immediate response in an NTR may be similar to a classic turbopump, in that increased flow will cause more heat removal from the reactor, thus feeding a proportional increase in power back to the turbine. The difference is how the power and temperature of the reactor change due to this increased pressure/flow, and how that will feedback to the turbine inlet power. The response of the reactor to a flow change is not proportional or linear, it is exponential. For most concepts, increased cooling of the reactor will increase reactivity, which will cause an exponential increase in power (or vice-versa), until the power of the reactor causes a temperature change to counteract that reactivity. For a neutronically simple reactor (one with simple reactivity coefficients, predictable heat transfer, and minimal neutronic worth of the H_2 gas), the feedback to turbine inlet power should be manageable; in fact it was essentially proven by the XE' test. The reactor for that NERVA test was indeed neutronically simple. Also, as mentioned previously XE' used hot-bleed cycle, plus the turbopump was open-cycle (turbine inlet flow was exhausted, rather than returned to the system flow); both of these features simplify dynamics even further. Alternatively, a system with large and/or uncertain feedback coefficients, uncertain heat transfer, and/or high H_2 reactivity worth, will have a highly unique and unpredictable response to the turbine. In that case turbopump control might be very complicated.

Cryogenic hydrogen storage

Liquid hydrogen boils at very low temperature, and it is usually stored at 20 K. It is very hard to keep anything with a view of the sun that cold in space, despite great progress over the years in developing insulation and reflective surfaces. The difficulty of storing Liquid Hydrogen (LH_2) is best evidenced by the fact that no on-orbit or deep-space satellite/rocket uses liquid hydrogen as a fuel, despite the substantial I_{sp} advantage of hydrogen. If in-space cryogenic storage was not a difficult engineering challenge, then in-space rockets would use H_2 instead of storable or hypergolic propellants.

For NTP, the refrigeration technology must be very reliable, long-lived and meet mass requirements; other than that, the technology should not be uniquely challenging because of experience with hydrogen storage on Earth and in-space cryogenic cooling. One additional complication is that nuclear radiation from the reactor will heat the hydrogen in the tank. In theory, this could be beneficial to keep the tank pressurized as the H_2 is discharged; however, there will be a good deal of uncertainty in the actual amount of power deposition (depending on the path and various shielding between the reactor and the tank). It might be better to provide shielding to ensure the H_2 does not overheat, as opposed to planning on a pressurization effect (although shielding requires mass).

Programmatic challenges

Nuclear launch safety

The possibility of an accident during launch or reentry from orbit provides a unique challenge for NTRs and all space reactors. From a technical perspective, the risks of radiation to the public are negligible (McClure, 2020), but public and political biases specific to “nuclear” could present a significant hurdle.

All fission systems that use uranium fuel are minimally radioactive prior to operation. There is negligible radiological risk to the public if there was a launch explosion (or other accident) that dispersed all of the fuel material into the air (the radiation risk to on-site personnel would also be negligible). The key to launch safety is ensuring that the reactor does not accidentally “turn on” (go critical and produce radioactivity) and subsequently provide a harmful radiation dose to anyone. Fission reactors are designed to critical with intentional/coordinated movements of control elements (to insert reactivity). Mechanisms must be engineered to ensure that the elements do not move inadvertently during any credible scenario; this is standard practice for every type of nuclear reactor, but space reactors have the additional issue of potential high speed impact and/or landing in the ocean.

Preventing inadvertent criticality is part of any space reactor design process. Some space reactor concepts can easily be designed to be inherently subcritical in all scenarios, including high speed impact and water flooding. This can be achieved by (1) minimizing the core volume that can be flooded with water, (2) keeping the core geometry very compact, (3) adding additional movable neutron absorbing safety mechanisms, and/or (4) incorporating materials which preferentially absorb neutrons during flooded/moderated conditions (commonly referred to as spectral shift poisons). The challenge for NTP is that a high flow area is needed for adequate heat transfer (a problem for option 1), the power is generally high enough to require a relatively large core volume (a problem for option 2), and the incorporation of moving mechanisms to prevent water immersion criticality is extremely difficult (a problem for option 3). If an NTR uses a moderated neutron spectrum, then an attractive system cannot be practically designed with spectral shift poisoning (a problem for option 4). The only NTR concept that can easily prevent inadvertent criticality during water immersion (by using spectral shift poisons like tungsten or rhenium) is an unmoderated reactor. Unfortunately this concept would likely have to use Highly Enriched Uranium (HEU) to have a practical mass, so in this case this safety challenge would have to be weighed against safeguards challenges.

Even if a concept does go critical (produce radioactivity) during launch/reentry accidents, the radiation risk to the public should still be extremely low. On land, it is more likely that a person would be harmed by the shrapnel of the reentering reactor and spacecraft rather than any possible radiation. During water immersion, water provides an excellent shield to radiation, such that a person would have to be within a few meters of the reactor to receive a harmful dose. Given the size of the ocean, the chance of anyone

being so close is miniscule; the only danger might be to personnel, if they are sent to retrieve the reactor. The launch approval process in the US allows for a probabilistic approach that could include these factors, so from a technical perspective launch safety should not be a major challenge.

The real challenge will be overcoming public and political bias to radiation and nuclear reactors. In this respect, an NTR concept that inherently prevents inadvertent criticality would be preferable than one that doesn't. The alternative is to try and convince decision makers that it's ok if the reactor goes critical if it falls in the ocean. It may be easy to show that it is almost certain that nobody will be harmed, but they still might not be willing to take the political risk of a nuclear "accident".

Nuclear ground testing

The biggest programmatic challenge of NTP would probably be performing a full-power nuclear ground test, because of the combination of high cost and the difficulty of gaining approvals. A facility that could adequately test an NTR would likely cost billions of dollars. The Rover/NERVA cost >\$10B in today's dollars, and a good fraction of that was spent on building and testing. More so, they had far less regulation, paperwork, and oversight than we have today, and had much more expertise and infrastructure.

The manufacturing and testing infrastructure that existed at the end of the NERVA program makes any nuclear development capability that exists today look miniscule. There were hundreds of design, manufacturing, fabrication, testing and system experts working on NERVA in the 1970s. Not only are most of these people gone, there has been relatively little knowledge transfer since this was before the era of digital record keeping, and use of the technology has not been continuous. Back then, nuclear development was more art and elbow-grease, as compared to science and CPUs; they built, tested and tweaked things and used their ingenuity to make things work.

The ability to get government approval for system testing is a major risk to an NTP program (whether the regulator is the NRC or DOE). NTRs have very small temperature margins and extremely high power densities, which are off-the-charts relative to any other successfully deployed reactor (certainly far beyond the scope of any potential regulator). The adiabatic heat-up rate for a typical 25-klb (klb = 1000 pounds of force = 4448 Newtons) thrust NTR might be ~1000 K/s. This is 50 times higher than a typical PWR, and higher still than a typical BWR. The implication is that if cooling is lost during powered operation, an NTR core would melt within seconds. Decay power is also a significant concern; 1 h after shutdown the adiabatic heat-up rate can still be >1 K/s. Another concern is that the testing also involves high volume of combustible hydrogen. All of these concerns are then amplified because the physics and dynamics that underly operation are very uncertain and unknown. There is a chance that an NTR testing program wouldn't even make it past the NEPA (National Environmental Policy Act) process. The worst case would be getting preliminary approvals, completing the facility, and then getting denied the approval to actually run the test. It would be important to avoid a situation similar to the Yucca Mountain Nuclear Waste Repository, which is sitting empty after billions of dollars of investment. The ability to get test approvals must be evaluated before any NTR concept is seriously pursued.

Another programmatic challenge that makes an NTR ground testing campaign difficult is time. Even a highly-optimistic, success-oriented program plan would require more than a decade. Given the realities of government funding, a program that takes over 5 years is risky and a program that takes over 10 years is essentially a non-starter (even the incredibly ambitious Apollo program went from conception to landing a man on the moon in 9 years).

All of the above difficulties are generally acknowledged within the current space reactor community, so attention has turned to possible flight-testing of NTRs, which would eliminate this programmatic challenge altogether. The flight-test option has become more attractive as the cost of earth-to-orbit launch has been decreasing. The caveat for flight-testing is that the NTR should have minimal system performance challenges (described below). A flight test would have limited ability to resolve diagnostic issues, and a limited propellant supply to resolve performance issues. Thus, the NTR concept chosen should have very simple and predictable performance. At a minimum, the very first system flown as part of a flight-test sequence would need to be very simple (Poston et al., 2019).

Nuclear safeguards

Every NTR that has been built, or gotten past the conceptual design stage, has used highly-enriched uranium (HEU) as the fuel. This is because HEU offer a lower mass, and a much simpler and potentially safer NTR system. Recent studies are considering low enriched uranium (LEU); specifically high-assay low-enriched uranium or HALEU, which is ~20% enriched in ^{235}U . This has the potential to save cost due to reduced security requirements and a simpler recovery effort if the system fails to reach orbit. The use of LEU also fits within a general US policy to avoid the use of HEU for civilian purposes whenever possible. The goal of these studies is to determine if a useful NTR can be successfully developed using HALEU, which would then provide an alternative to a simpler and higher performance HEU system. If it is ultimately determined that HEU is strongly preferred for an NTR project, then the challenge will be to overcome any policy objections to the use of HEU. Current laws and regulations do indeed allow for the use of HEU for space reactors (the recent NASA/NSSA KRUSTY space reactor test (McClure et al., 2020) actually used HEU, including transport across the country). Also, several plans and procedures exist to provide robust security from fabrication to launch, which is why policy decisions are the only significant obstacle.

System performance challenges

There are several technology and programmatic challenges described above, but the greatest challenge to NTP development might be achieving the desired performance of the integrated system. The unique combination of technology challenges coupled with the

difficulty of nuclear system testing makes it extremely difficult to predict, test, and correct performance issues. System performance describes both steady-state and transient operation, the potential for instabilities, and the mass and flexibility of the system: e.g., restart capability, electric power generation, off-nominal operation, etc.

System performance challenges depend greatly on the specific NTR concept. Performance risk depends on the number, magnitude, and uncertainty of reactivity feedback coefficients, the number of flow passes through the core, the uncertainty of heat transfer paths, the uncertainty in turbopump outlet conditions, etc. Risk is also a function of uncertainty in instrumentation and control components, and how much system performance depends on proper I&C function. Integrated simplicity and lack of reliance on fast acting control are both very desirable in this regard. The “challenge” may actually be to find a combination of performance requirements that allows a simple NTR concept to be pursued.

There are a large number of uncertainties in neutronic, thermal, and mechanical performance, and in most cases they compound each other. For a first-of-a-kind engineering system, it is probably better to have 1 or 2 large independent uncertainties, then several smaller uncertainties that can exacerbate each other. An NTR concept that has the simplest combination of uncertainties among all areas is the most likely to avoid performance challenges. Also, as NTR development proceeds, several changes to components and design will occur as issues are resolved, and it is very likely that the performance of individual components will diverge for the original design point; the result might be a system that does not operate as intended, or operate adequately at all.

The key parameters that dictate system operation are reactivity feedback, component-to-component heat transfer, and the inlet flow conditions (i.e., variability in H_2 temperature and pressure, which is largely dictated by turbopump behavior). Most of the challenges involving heat transfer and the turbopump were discussed earlier. From a nuclear perspective, an NTR will be in a different operational paradigm than almost all prior reactor experience. The combination of materials is not only unique, but the potential temperature range of components is also outside normal experience (both at the cold end $\ll 300$ K and the hot end $\gg 2000$ K). There will be a significant uncertainty in nuclear data, which to some extent can be resolved via zero power criticals testing, but not over the full operating range, and probably not with the combined effect of high pressure hydrogen. The level of uncertainty in nuclear data will depend greatly on the concept that is pursued, in particular its neutron spectrum. The reactor isotopics and spectrum also effect the ability to restart an NTR within in a relatively short time (< 1 day), depending on how sensitive reactivity is to the buildup of the fission product ^{135}Xe .

Dynamic performance can become even more unpredictable because the uncertainties also effect the time constants at which components react to change. Stable reactors will nominally overshoot and undershoot steady-state conditions, and the magnitude of these oscillations depends on numerous factors. An advanced instrumentation and control system can operate in real time to mitigate overshoot, but this kind of development would require ground testing (i.e., an essentially unlimited supply of H_2 to slowly startup and investigate how the reactor responds). The variability and uncertainty of feedback, heat transfer, turbopump output, and time constants will also increase the chance for instabilities throughout the operating regime. Inherent instabilities can be controlled, but an NTR that requires real-time reliable signals and actions to keep the system under control has a huge safety and development disadvantage versus a system that operates passively in the nominal operating regime (i.e., standard reactor practice). During the Rover/NERVA testing they discovered operating regimes where the systems were unstable, and then they were able to avoid those regimes in subsequent tests.

Present day modeling capabilities are more advanced than in 1970, but we are still nowhere close to adequately modeling the dynamic performance of a complex NTR. Our capability to perform transient modeling on any first-of-a-kind reactor is extremely limited, despite major efforts in multi-physics modeling over the years. Transient calculations can be reasonably estimated for simple systems, like KRUSTY, because of simple feedback, relatively simple heat transfer, and the valid application of point kinetics (Martin, 2021). An NTR is potentially harder to model than any type of reactor, because of the importance that the turbopump plays in system dynamics, the modeling of compressible flow, and the need for very small computational time steps (due to the high flow velocity).

Experience during the NERVA program has the potential to help diminish system performance challenges, but this depends on how similar an NTP concept is to the tested NERVA rockets. Some of features that made NERVA rockets simple were: the lack of neutron moderator, the lack of multi-pass flow regions in core, the use of an open-cycle turbopump, the use of a hot-bleed cycle to power the turbine, relatively low temperature coolant outlet (2270 K), relatively low coolant reactivity worth, the presence of only one dominant reactivity feedback mechanism (i.e., fuel temperature), and the lack of uncertainty in most parameters due to numerous prior test iterations. The best option for future NTP programs might be to use the same approach as NERVA by simplifying system performance as much as possible; this could be accomplished by using an unmoderated HEU reactor. An unmoderated HEU cermet (ceramic-metallic) fueled reactor should provide the simplest system performance, while also providing the best option for launch safety (Poston, 2018).

Summary

Nuclear thermal propulsion is a high-reward, high-risk technology; i.e., the benefits are great as well as the challenges. The greatest near term benefit is for human travel to Mars, and future human and robotic missions could benefit as well. The greatest challenge is a large number of unproven technologies combined with a limited ability to perform full system testing. For a useful NTP system to be deployed, it will likely require evolution from much simpler space reactors, or a sustained program with a Rover/NERVA level of effort.

Introduction

The idea of using nuclear power to propel a spacecraft is a concept almost as old as either nuclear power or rocket design. Radium-powered interplanetary propulsion was proposed in 1913 by Robert Esnault-Pelterie ([Esnault-Pierre, 1913](#)); others were also investigating the use of nuclear power for spaceflight as well. However, it would be the Manhattan Project that would enable the first major work on nuclear thermal rockets (NTRs).

The United States was the first country to put significant resources behind developing NTR into a functional technology rather than a promising concept, starting as part of the Nuclear Energy for the Propulsion of Aircraft (NEPA) program in 1946 ([Schreiber, 1956](#)). This broad research program would be separated into different, more focused programs, with NTR development becoming Project Rover in 1955; the primary facility for NTR development became Los Alamos Scientific Laboratory in Los Alamos, NM starting at that time. Project Rover's development program became more focused under the Nuclear Engine for Rocket Vehicle Application (NERVA) program in 1961 ([Robbins and Finger, 1991](#)). NASA, the AEC, and civilian contractors worked to develop a flight-ready NTR to support post-Apollo crewed missions to the Moon and Mars. Sadly, both Rover and NERVA would be canceled in 1974, concurrent with the elimination of many parts of NASA's plans for further crewed spaceflight ([Portree, 2001](#)).

Starting in 1955, the Soviet Union would devote significant resources to a nuclear thermal rocket program of their own, and would continue to work in the field until the fall of the USSR ([Wetch et al., 1991](#)). Their efforts focused on more promising (but less well-understood) fuel element materials, and used an easier-to-test geometry in their design, so development followed a slower and more modular the American effort, with one of the earliest designs being consistently developed for the majority of the life of the program.

With very little funding for any astronuclear research in the US after Apollo (with one notable exception), and the financial crisis with the fall of the USSR, NTR development was largely relegated to individual design studies, concept development for both improvements on the tested models of NTR as well as more advanced designs, and materials development for various reactor components. Advances in computational capability (both in terms of simulation design and computational power) have led to many proposals for designs, but these have been limited by both the lack of a specific mission to justify the high expense of NTR development and the lack of a specific mission requirement for such a system.

Early US NTR efforts

The first published example of the nuclear thermal rocket was in 1946, when Robert Serber of Douglas Aircraft published "The Use of Atomic Power for Rockets" ([Serber, 1946](#)). Other publications followed in short order, but the highly secret nature of all nuclear technology at the time meant that it was not unusual for almost every study to start from first principles ([Schreiber, 1956](#)). In the earliest days of nuclear rocket research, a huge number of designs were proposed, most of which had a wide variety of variants in how they would be executed. Many of these designs are quite advanced by the standards of the nuclear rockets currently being proposed for active research, but have been either starved of funding or forgotten, sometimes for decades. One thing of note is

the wide variety of proposals, from reasonably conventional high temperature gas cooled reactors of various types, to reactors designed to vaporize themselves during operation, the use of nuclear explosives for propulsion, early nuclear electric propulsion proposals, and many other design architectures. This was due to the lack of communication from the various groups, and the requirement to begin from first principles.

One early source of funding was the Nuclear Energy for the Propulsion of Aircraft (NEPA) Project, which looked at a variety of propulsion methods—including pure rocket propulsion. Nuclear thermal designs were often based on a first stage for an upgraded, nuclear powered V-2 type rocket (being tested at the time at White Sands Missile Range in New Mexico, US), rather than for propelling interplanetary missions.

Within a reasonably short period of time, many American design programs for both aircraft and thermal rocket research settled on the use of a high temperature graphite matrix for the fuel element. This was considered the most mature form of fuel available, and able to give the surest results. Refractory metal fuel elements also showed promise, but the lack of manufacturing knowledge with regards to these metals meant additional uncertainty about their developmental timeframe. Because of this, most programs focused on the more easily manufactured graphite fuel elements, and in particular how to protect them from the highly corrosive hot hydrogen environment they would be exposed to during operation. Fuel element geometry ranged from arrays of hollow pipes to plates to various basic shapes with holes for the propellant drilled through them. This variety of fuel element designs would remain a hallmark of nuclear thermal rocket designs to the present day.

This design decision also led to another major focus of many NTR designs: the fuel clad. Due to the highly corrosive nature of most of the propellants used, the fuel would need to be protected by a coating of some high-temperature material able to resist hydrogen (the most efficient propellant available). The design, fabrication, and testing of clad materials would remain a major focus of work on most NTR programs (Schreiber, 1956).

The beginning of the space race: NASA and Rover

The best known NTR development program was Project Rover, which started in 1955 as a joint United States Air Force (USAF) and Atomic Energy Commission (AEC) program. The USAF portion of the program was transferred to the National Aeronautics and Space Administration (NASA) when that organization was created in 1958. Over the next 19 years, Rover would be the most extensive (and intensive) NTR testing program in history, and would result in system claimed as flight-ready by the time of its cancellation in 1974 (Robbins and Finger, 1991).

Early in the program, there were two primary designs, using different fuel element geometries, fuel element matrices, and flow paths.

Kiwi type reactors featured a uranium oxide particle fueled graphite plate, rod, or prism, usually with holes drilled through the axial length, to form the fuel element. Hydrogen propellant flowing through the reactor from end to end provided both cooling and neutron moderation. The number of fuel element geometries available was wide, and the same basic reactor geometry could be used with minor modifications for a number of other fuel matrix materials, such as refractory metal or carbide fuel elements. The uranium oxide could also be changed to uranium carbide to increase exhaust temperature (Schreiber, 1956).

Dumbo type reactors used corrugated sheets of uranium oxide embedded into a beryllium metal matrix to increase heat conduction over what graphite offered. Stacks of these fuel sheets would create individual flow paths, and the reactor's power and physical size could be adjusted by varying either the number of fuel stacks or the length of the fuel stack. Another distinct difference was the radial flow through the heat exchanging portions of the reactor core to allow for more even heating of the reactor across its entire major axis, and utilized laminar flow throughout the flow path. This offered the benefit of being able to test a small portion of the reactor in easier-to-conduct tests and have high confidence in the results for a full system. In addition, the reactor contained colder zones along the entire axial length, allowing for the more even distribution of lower-temperature materials than the Kiwi-type reactor (Knight et al., 1957).

Both reactors would be investigated at the beginning of Rover, with preference for the Kiwi-type reactors. These were better understood from a manufacturing point of view, and leveraged the already-existing research into fuel element fabrication and core design. The Dumbo design offered better performance, potentially easier nuclear and flow path testing, and greater modular flexibility. However, the lack of experience with the “metal” fuel, as it was known then (this fuel element type, which uses a ceramic fissile component in a metal matrix, is usually called CERMET today), was a concern. Additionally, there were significant computational challenges in ensuring that the flow through the reactor system would indeed remain laminar throughout the flow path. In 1957, the Dumbo design was defunded, and all research efforts would go into the Kiwi-type design and its successors (Kirk, 1992).

The testing of the future NTRs of Project Rover went through several steps. The first was gross core geometry configuration: a test stand called Honeycomb was used to easily replicate the general characteristics of a reactor core using square blocks of materials of several types (fissile fuel, moderator, reflector, neutron poison, and others) to create a sub-critical “sketch” of the reactor core. The core configuration was generally split into two halves, which would be brought together to test zero-power criticality, or the bare minimum requirements to test whether a core would be critical, the basics of reactor dynamics within the proposed core configuration, and other core characteristics.

Once the Honeycomb mockup demonstrated that a design was worth pursuing, the next step was a rough “zepo,” or zero power, mockup of the core. Because this was an experimental criticality test-bed, which wouldn't be put under any strenuous testing, the

machining was not as high quality as the following reactors—only good enough to verify that the initial Honeycomb tests were correct.

A finer-machined mockup, known as “ZEPO-fine,” was then constructed, to verify that the configuration was adequate for the manufacture of the final test reactor, as well as allowing the fabrication personnel to have a better idea of potential manufacturing challenges.

Finally, the NTR that would be hot-fire tested went through a series of criticality, zero power, and cold flow testing to verify that the configuration behaved as predicted, and to assess the reactivity worth of the individual components. This also served to verify the hydrodynamic properties of the reactor, and to calibrate any mechanical erosion issues from propellant flow, mechanical motion of the individual components, and other possible issues with the design (Paxton, 1981).

The reactor would then be transported on a custom-built rail car (which also served as a test stand) to the Nuclear Rocket Development Station at Jackass Flats, NV, where facilities for testing and post-test evaluation were constructed. There, the reactor would be integrated to the NRDS facilities, undergo a final set of checks, and then undergo fission-powered testing. Depending on the reactor, anywhere from 1 to 50 reactor tests would be carried out, at a variety of power levels, temperatures, power and propellant transient conditions, and durations.

After the completion of hot-fire testing, a hot cell laboratory at the NRDS, the Engine Maintenance and Disassembly facility, would be used to disassemble and examine the reactor. This would include: fuel element mechanical, radiological, and chemical analysis; control system mechanical analysis; nozzle damage analysis and a host of other tests (Finseth, 1991).

Hot fire testing: The experimental reactors

Kiwi

Kiwi A Prime pre-hot fire integration at the Nuclear Rocket Development Station. Image U.S. Department of Energy public domain.

The first (or A) generation of Kiwi reactors were experimental designs, designed for basic materials testing and component design experience rather than attempting to build a functional rocket. Because the reactor wouldn't be used as a flight model, and due to the rarity of fissile material at the beginning of the program, a design was decided that was strongly heterogeneous. The first Kiwi reactors used a low pressure heavy water (D₂O) “island” in the center of the core as a strong moderator, which allowed for lower fissile fuel content. These reactors also utilized gaseous hydrogen as a coolant, since cryogenic hydrogen technologies were still undergoing experimental development and not available at the test facility for hot-fire testing of these engines. Many of the tests focused on the basics of reactor control dynamics, fuel element materials and manufacturing techniques, and other broad questions about NTR technologies.

A total of three reactors in this series (KIWI A, A', A3) were hot-fire tested from July 1, 1959 to October 19, 1960. These early tests had many issues, from fuel element erosion due to hot hydrogen interactions, to broken fuel elements due to vibration and thermal stresses, to other reactor components being damaged either thermally, chemically, or mechanically during these relatively short

tests. New fuel element geometry and clad technologies (both materials and manufacturing methods) were continuously applied, and much of the information that was gained during the early program helped significantly inform the following reactor designs.

Kiwi B4 A upon arrival at the Nuclear Rocket Development Station. Image US Department of Energy public domain.

The second series of reactors, Kiwi B, ran from December 7, 1961 to September 10, 1964, and involved hot-fire testing of five different reactors (KIWI B1A, B1B, B4A, B4D, and B4E). While the number of design changes from the "A" series reactors was significant, the largest change in reactor core geometry was the elimination of the D_2O island in the center of the core. In addition, with the exception of the B1A reactor, all Kiwi B reactors used liquid H_2 , rather than the gaseous form, to match the thermal, density, and moderation environment that a flight system would experience (the B1A and B1B reactors were virtually identical except in the use of LH_2 instead of GH_2 coolant).

The B4A was the first reactor to use the hexagonal prism fuel form common to many NTR designs, replacing earlier cylindrical fuel elements held in graphite mounting structures. While the specific geometry of this type of fuel element would continue to change over the course of Project Rover and into the present day, this general fuel form would remain a mainstay of many American NTR designs.

The final reactors in the series (B4D and B4E) was notable in a significant way: was the first hot fire test to show significantly reduced fuel element damage when compared to other reactor tests. Up until this point, the majority of tests were shut down early due to fuel element failure, with mass being ejected from the reactor core during operation in many tests (seen as bright flashes in the exhaust stream). Careful redesign and cold-flow testing following the B4A test, as well as redesigning the thermal and mechanical design of the core components, managed to eliminate this persistent problem. The B4E was also the first widespread use of uranium carbide as the fissile component of the fuel elements, rather than the oxides that had been used up to this point, increasing the thermal stability of the fissile fuel and therefore the theoretical operational temperature of the reactors (Finseth, 1991).

The final test in the Kiwi series of reactors was highly unusual: the Transient Nuclear Test (KIWI-TNT) was a special flight safety test (based on the B4E reactor) to determine sudden power transient behavior of an NTR should it experience a chemical booster explosion or failure to orbit resulting in the immersion in water of an NTR, as well as testing potential in-space decommissioning possibilities using the reactor's power to force a rapid disassembly of the system. In order to meet the requirements of a runaway chain reaction, the reactor's control systems were heavily modified to increase reactivity insertion rates, fission poisons used in the core to balance the neutron spectrum in the core were removed, and a host of other modifications to the core neutronics to eliminate all safety margins were made. The reactor was then forced to undergo rapid deconstruction through thermal overload: they forced the reactor to blow itself up. It's important to note that this was not something that could occur in a standard Kiwi-derived reactor (Fenstermacher et al., 1965). This test was the only one of its type ever conducted, and provided valuable data to mission planners and engineers,—at the cost of significant environmental impacts in the region (Fultyn, 1968).

Phoebus: The transition to development

Phoebus 1A undergoing installation at hot fire test stand. Image US Department of Energy public domain.

Phoebus was a short program, only involving three hot-fired reactors, all based on the Kiwi B4E reactor. This program, while technically experimental, had many similarities to a development reactor program, since they were all based on the same reactor, with the same end goal: develop the Kiwi technology to a point that it could undergo developmental, rather than experimental, experimentation.

The main differences between Kiwi and Phoebus were in fuel element design, specific impulse improvements, power density of the reactor, and power level of the reactor. The end goal of the program was a 5000 MWt reactor, using improved fuel element design and enlarging the coolant channel diameter.

The Phoebus 1A, the first reactor, was damaged during the hot fire test on June 25, 1965, because the test stand ran out of hydrogen, permanently damaging the system. This cut the planned testing of this reactor short, and necessitated the next test of the 1B (as well as an emergency hydrogen dewar backup at the test facility). This reactor was similar to the 1A, except it achieved a higher power level (1500 MWt rather than 1050 MWt), and ran for 46 min on February 23, 1967.

The Phoebus 2A was a much more powerful reactor, and underwent four test runs from June 8, 1968 to July 18, 1968. It achieved a final power level of 3500 MWt in its final test, making it the most powerful NTR to ever be tested in a hot fire stand, and twice the thermal power output of any high-temperature gas cooled reactor used for electricity generation on Earth. Despite this huge power output, this was meant to be an intermediate power reactor on the development path to the ultimate goal of 5000 MWt, and incorporated many improvements in reactor design in order to achieve these higher power densities. Perhaps the second most noteworthy part of the Phoebus 2A's design was the incorporation of a new concept in NTRs: about 10% of the hydrogen was diverted through the fuel element support structures instead of being fed into the fuel element coolant channels, increasing the hydrogen content of the reactor and allowing for the use of more thermally limited support structures (Finseth, 1991). This is the tie rod, which was used for core structural support for all follow on reactor tests. Later, a more advanced structural element called a tie-tube was considered, which proposed returning the hydrogen flow back through the core to improve efficiency, but this was never tested in a reactor. Tie tubes are now commonly proposed in many NTR designs that use hexagonal fuel elements, and have undergone some lab-scale technology development (Benensky et al., 2015).

Pewee and nuclear furnace: Economical fuel element development reactors

Pewee being delivered via the NRDS locomotive to the test stand. Image US Department of Energy public domain.

By this time, the cost of constructing full-sized experimental reactors in inflexible configurations was becoming a significant burden on the program, and so the experimental testing of NTRs turned to smaller, more adaptable designs. The first of these was Pewee, a small (500 MWt) NTR design, which while similar to the Phoebus designs placed a moderating sheath of zirconium hydride around the tie rods to allow a far smaller core size. This reactor was indeed far less expensive than its predecessors, and achieved impressive power density and specific impulse (except this was not designed for, since this reactor was not meant to be a flight model).

The Pewee was tested three times from November 15 to December 4, 1968, and continued to improve fuel element design, both in improvements to fuel clad and coolant flow volume in the elements themselves. It met all of the experimental requirements for the program, and was considered for potential further use as a test platform, but this did not come to pass (Finseth, 1991).

The legacy of Pewee lives on, however. Most current NTR designs are approximately the same thrust level as Pewee could have achieved had it been flight optimized—in fact, many NASA papers use the term “Pewee-class” for these smaller NTR designs, which are usually used in proposals as a cluster of three engines.

The other reactor used for advanced fuel element development was the Nuclear Furnace, a reusable, cost-effective method of testing multiple types of fuel element at once. Unlike all of the experimental reactor designs up to this point, the Nuclear Furnace test was not configured as a rocket engine. Rather, it was designed as a more traditional experimental reactor (albeit based on the Pewee pressure vessel), allowing for replicating the neutron flux, thermal and chemical environment that a fuel element would experience in an NTR, and allowed for more configurations of fuel elements to be tested at the same time. It was also designed to be easily reusable and inexpensive to test, incorporate components from previous programs, and to test an exhaust filter for the hot hydrogen gas to scrub out radionuclides and other contaminants.

This reactor was engineered so that major components of the system would be reused, with only the central core structure (which held the fuel elements) and the effluent filters would need to be replaced. It also was designed with far fewer fuel elements—rather than the hundreds or thousands of fuel elements used in the previous tests, the Nuclear Furnace only had 47 advanced carbon composite fuel cells (UC-ZrC)C spread through a carbon matrix, and two fuel cells each containing 7 smaller, pure (U,Zr)C carbide fuel elements. This in turn required more moderation of the reactor to run with so little fuel, so water was used as a moderator in addition to the hydrogen coolant, with a beryllium reflector and control drums completing the neutronic features in the reactor (Finseth, 1991).

After being heated in the reactor, the hot hydrogen was passed through an Effluent Cleanup System (ECS). The ECS used a system of wire meshes, dehydrators, coolers, and a charcoal trap filter to capture the radionuclides released during the test, and operated very successfully during the test. This was the first implementation of a design concept for testing that would be required in all post-Rover NTR hot fire test programs, however subsequent test concepts have required much larger and more complex ECSs to meet the much higher hydrogen throughput that a full sized NTR under full power for extended operations would require.

The reactor behaved as expected, and the disassembly of the reactor went smoothly, indicating that the reactor concept would in fact be reasonably easy to reuse. The filters also showed very predictable behavior, meaning that if longer test durations were needed the modifications to the filter would be simple to design and implement (Kirk et al., 1973).

There was only ever a single test series of 10 hot firings using the Nuclear Furnace, NF-1, on June 29 to July 27, 1972, which also marked the end of hot fire testing in Project Rover.

NERVA: Building a flight-ready NTR

NERVA A3 undergoing integration at Kiva C at Los Alamos Scientific Laboratory before being delivered to NRDS. Image US Department of Energy public domain.

Once the basic technologies involved in an NTR were demonstrated to both NASA and the AEC, a program was begun to develop a practical, flight-worthy NTR for use in advanced Apollo missions and beyond. This program was named, Nuclear Engines for Rocket Vehicle Application, better known by its acronym: NERVA. While still a component for the overall Project Rover, this was a distinct program with its own goals and technological development based on the successful Kiwi B4 reactor design. The reactors would be informed by the ongoing Phoebus, Pewee, and Nuclear Furnace experiments, but would use better-developed, less experimental versions of the technologies that were still being advanced at a breakneck pace in the larger Rover program. Begun in 1956, this program would continue until the cancellation of US NTR development in 1974 ([Robbins and Finger, 1991](#)).

The first set of NERVA tests were the NRX, or Nuclear Reactor-Experimental, series. All reactors were a development of the Kiwi-B4, although the flow of coolant through the reactor vessel and reflector was changed to increase cooling of the reactor components. Other changes included modification to the nozzle design and fuel elements (both ongoing design evolutions during the NRX program), improved mechanical strength of the core, and increasing power density in the core.

NRX-A1 was used for cold flow and manufacturing testing, and was not hot fired at the NRDS. NRX-A2 was tested on 24 September 1964, being the first reactor to operate at full power (for a total of 6 min). This test was followed by the A3, which was tested three times from April 23 to May 28, 1965.

Following the successful A2 test, the first breadboard test of an NTR was conducted (i.e. using flight components, but not in a flight configuration). This was the NRX-EST test series (consisting of 11 firings), and it occurred between February 3 and March 25, 1966. This was also the first time that an NTR used its inherent core reactivity to facilitate reactor startup (a process known as bootstrapping). With these milestones achieved, the NRX-EST demonstrated that an operational NTR based on the Kiwi B4 could be achievable in the near term, and depended less on the technology than on mission requirements from NASA.

The next reactor to be hot fire tested was the NRX A5, which underwent two tests from June 8 to 23, 1966. After a few false starts, the testing showed that many of the development issues with the fuel elements themselves had been largely solved, although some challenges remained for the design of the fuel elements. This was the last of the NRX series of reactors, and ended the hot fire testing of these NTRs with a resounding success. The fuel elements of this reactor would be used in the XE-Prime flight system test, despite being superseded with more advanced elements in both Pewee and Nuclear Furnace testing, because of their successful behavior in testing, and their relative technological maturity (Finseth, 1991).

XE-prime: Testing the flight configuration

NERVA XE-Prime being delivered to NRDS in vertical orientation. Image US Department of Energy public domain.

XE-Prime was the final major test of NERVA, and as such was designed to mimic the flight configuration of an NTR as closely as possible. By this point, the development of the NERVA NTR made sense to divide into two parts: fuel element development and flight configuration verification.

While fuel element development could be continued using test stands that only mimicked the environment of an NTR reactor core, the flight configuration verification tests had to be as close to prototypical as possible. This meant a number of things had to

occur: all of the components of the engine system had to be in the same relative location as they would be on the flight engine, and the test needed to be conducted with the nozzle facing down, rather than the inverted configuration that all testing had been conducted in up to this point. A nearly year-long test program was carried out under these conditions at NRDS: XE-Prime. While the majority of the flight components of XE-Prime were the final design choices, the fuel was identical to the Kiwi A5 reactor, a less advanced but still adequate nuclear fuel. This means that fuel element performance on the XE-Prime test would not be as effective as the final flight system would be in terms of fuel lifetime, erosion, and potential cracking, but were sufficient for this test (Finseth, 1991).

The XE-Prime reactor was first fired on December 4, 1968, and the final firing was on September 11, 1969. A total of 24 hot fire tests, grouped into 10 experimental programs, were conducted during this time. Many of these experiments focused on start-up and shut-down procedures for an NTR, as well as reactor control system characterization, instrumentation requirements for the flight system, test stand validation, and finally post-test remote handling equipment and procedures for the post-test examination of the test article. Despite some difficulties with starting the engine under particular reactor conditions, as well as instrumentation and accidental scram (emergency shut-off) events, the testing program completed its objectives.

With these successful tests complete, focus would shift back to fuel element development as part of the Pewee and Nuclear Furnace programs in Rover. However, another flight configuration NTR was never hot fire tested in the US after 1969.

Funding, politics, and the end of NERVA

Project Rover and NERVA were always viewed as being used for the next steps after the Apollo missions: establishing a lunar base or crewed missions to Mars. While various organizations, such as NASA and the AEC, supported Project Rover, often the impetus for funding the program came from the political arena, with US Senators for the various locations involved in the program ensuring that funding would be made available and the program would not be canceled. This was especially true during the early days of the program, when fuel element failure was not only routine but expected. However, the combination of it being advanced technology, and highly politically dependent for its survival regardless of its technical merits, meant that the NTR program in the US had the potential to be rapidly canceled if political considerations changed—which in 1972 they would.

At its peak in 1965, Rover had a budget of \$181.1 M USD, but by 1967 had shrunk to \$140.3 M USD. In August 1967, Congress removed all advanced planning, a Mars probe program, and all funding for NERVA, but funding was able to be restored for the program for \$127.2 M USD, with the NRX A6 performing the first 60 min test at the end of the year. However, this was only a temporary reprieve, as the US involvement in the conflict in Vietnam became a larger burden (both in money and lives) leading to significant budget cuts, the administration changed political parties, and new priorities, namely what would become the Space Shuttle and International Space Station in the coming decades, all made NTR technology irrelevant for the direction the US was looking to with its space program. In fiscal year 1972, the combined funding from both the AEC and NASA for NERVA was only \$30 M USD (as opposed to the \$110 M requested), despite Congress offering \$81 M USD in funding for the program. The 1973 budget completely eliminated NERVA funding, and 1974s eliminated all nuclear rocket research funding for all programs (Portree, 2001).

This cancellation would lead the US NTR efforts into an extended period of low activity. While design work on advanced systems, both with different fuel types and different core geometries, as well as materials development, would be carried out, these programs were small, not well funded, and resulted in a relatively small amount of experimentation and testing. Despite some of these designs achieving a level of theoretical development where experimentation would be necessary to further the design, this would not change in any significant way until the Strategic Defense Initiative in the early 1980s.

The legacy of NERVA

Project Rover and NERVA remain the most well-known and extensive testing programs of an NTR system ever conducted. The number of engines, and number of hot fire tests those engines underwent, remains unsurpassed by any other program. By the time of the program's cancellation the NERVA-XE engine was considered flight-ready, the only US NTR system to reach that level of development (Robbins and Finger, 1991). The results of these testing programs are still used in many computational models for NTR design, and the program became synonymous with NTRs in general in the US.

NERVA-derived NTR designs have been proposed since its cancellation, most notably the Small Nuclear Rocket Engine (SNRE). This design uses an advanced version of the Pewee engine, with carbide fissile fuel distributed within a carbon-carbon fuel matrix (Borowski et al., 2015), and is a derivative of the NERVA Derived Reactor (Clark et al., 1992). Several variations of this design, including the Criticality Limited NTR (an even smaller NTR, designed for interplanetary probe missions and flight-proof-of-concept testing), the Lunar Oxygen Augmented NTR (LANTR) hybrid nuclear-chemical engine, and various sizes and power outputs of the original SNRE concept, have been proposed since (Borowski et al., 2017). However, none of these systems have been built or tested, and non-nuclear component testing has been financially limited. Most modern proposals have moved away from the NERVA-legacy graphite/C-C composite fuel matrix in favor of either a ceramic-metal composite (CERMET) or carbide fuel form.

Project Timberwind: The rebirth of US NTR development

The next major NTR program in the US was Project Timberwind, a uranium carbide fueled pebble bed NTR. Initially a part of the Strategic Defense Initiative, this program began in 1987, and was transferred to the US Air Force's Space Nuclear Thermal Propulsion

program in 1991. Development of both the reactor itself and the testing facilities required for hot fire testing continued until its cancelation in 1994.

As with all pebble bed fueled, gas cooled reactors, the increased surface area of the fuel increases the thermal transfer capacity from the fuel to the propellant. The design used two perforated cylinders, called "frits," to contain the fuel particles, which measured 0.5 mm in diameter. Being fueled by a solid solution of carbides, the maximum fuel temperature was increased, and therefore the exhaust temperature (and specific impulse) were increased accordingly. Additionally, due to the high thermal transfer rate, the reactor could theoretically produce more power per unit volume without undergoing thermal failure, leading to a more compact and lightweight design. This allowed for a significant improvement of thrust-to-weight ratio, allowing for greater flexibility in mission application.

Criticality, cold flow, and other testing of the Timberwind fuel elements were conducted at Sandia National Laboratory, Brookhaven National Laboratory, the US Air Force Phillips Laboratory, and other facilities, laying the foundation for additional component and systems tests.

Preliminary design reviews for the engine and upper-stage vehicle were conducted from 1987 to 1989, focusing on the NTR's use as part of the Boost Phase Intercept vehicle concept. With the transfer from SDIO to the US Air Force, this was de-emphasized in favor of a more general mission profile for multiple USAF space missions (Haslett, 1995).

The primary challenge of this program was designing and funding testing facilities for engine hot fire testing. Directly venting the propellant into the atmosphere, as was done for the majority of Project Rover, was no longer an acceptable method of hot fire testing, so an alternative needed to be found. Initially, the design of the testing facility focused on capturing all of the heated hydrogen propellant in a large system of tanks, but this concept was both expensive to construct and severely limited the testing duration available due to volumetric constraints. At the end of the program, underground testing of sub-scale nuclear systems which would be able to be directly applied to a flight test were proposed, in order to reduce test facility costs (Allen et al., 1993).

Project Timberwind was canceled in 1994 with the end of the Space Exploration Initiative, with cost being a primary driver for the decision. According to the Project Timberwind Final Report, the program cost would be approximately \$1 billion USD (1995 value), with potential flight testing to be conducted in the year 2000. This long lead time, the cancelation of the SEI, and the ballooning costs of testing the system led to the decision to cancel the program (Haslett, 1995).

Soviet NTR history

The Soviet Union started focusing on the development of nuclear thermal rockets starting in 1955. Multiple design bureaus across the country worked on the design and fabrication of the initial nuclear rocket engines (NRE), the preferred term for nuclear thermal rockets in Russia. This included the Kurchatov Institute of Atomic Energy (KIAE), the Research Institute for Thermal Properties (NIITP), the Institute of Physical Energy, Moscow (IEE), and Scientific Industrial Association, "LUCH," in Podolsk (Wetch et al., 1991).

The initial (and sustained) focus of this program was on a heterogeneous reactor design, unlike the more homogeneous core that was focused on in the US. These used active regions containing the fissile fuel and propellant flow at high temperatures, and passive, moderating regions kept at a lower temperature between the active fuel bundles. This offers the advantage of allowing for a more thermal neutron spectrum in the reactor, similar to the way the early Kiwi reactors in the US used a low pressure D₂O region. However, by increasing the fissile fuel density of the active region, the total power density of this type of reactor was higher than a homogeneous reactor of the same power level. By using zirconium hydride as a moderator, and separating the heated propellant flow from the thermally sensitive ZrH, it was possible to design an NRE that had good power density, excellent specific impulse and thrust, and was able to be tested using even a single fuel bundle in one of two research reactors that were built for NRE testing at the Baikal Research Reactor Complex in Kazakhstan.

Additionally, rather than using the graphite matrix fuel elements used in the US designs, the Soviet engineers decided to go immediately to a carbide fueled NTR/NRE. This allowed them to target a fuel temperature of 3000 K immediately, close to 500 K higher than the equivalent US system at the same time. This was an option that was considered in the earliest days of the US NTR program, but was rejected for the initial stages of Project Rover due to the unfamiliarity of the established industry with carbides as used in fissile fuel (in later NERVA fuel elements, and some experimental fuel elements tested during the Nuclear Furnace test, carbides were actively employed, but this was so late in the program that it had little overall effect on the technological development of Rover/NERVA systems as a whole). The Soviets, on the other hand, decided that the most promising technology was the one worth pursuing, even if it led to a longer development time. They developed a ternary carbide fuel form, made up of UC-ZrC-NbC and UC-ZrC-C. This allows for a maximum operating temperature of 3200 K, increasing the specific impulse of the NRE significantly (Zakirov and Pavshook, 2007).

The hot fire testing program for the NRE started in 1970, and 30 firings would be conducted by the time the program ended in 1989 as a result of political and financial challenges in the USSR. A total of 330 fuel bundles were successfully tested in 24 successful hot fire tests. However, due to the modular nature of the reactor, the independence of the fuel element bundles for propellant flow, heating, and other characteristics, neither a bread-board (i.e. constructed out of flight components, but not in flight configuration) or flight configuration hot fire test occurred for any Soviet or Russian NRE.

These advantages to the USSR's design made it a robust, flexible, scalable system, allowing for both smaller and larger NREs by varying the number of fuel bundles and the amount of moderation in each design. This design is apparently scalable from ~20 to ~980 kN of thrust with a specific impulse of around 950 s. The most common designs are a small, ~20 kN NRE, which would be

able to propel an interplanetary probe and provide an initial mission for the propulsion system; a larger, ~ 35 kN engine called the RD-0410 for crewed missions; and finally a very large, ~ 390 kN NRE, the RD-0411, which would be used for large crewed missions. Each of these designs is based on the same fuel element bundles, moderator blocks, and control systems, with minimal modifications to account for reactor dynamics changes due to reactor scaling (Zakirov and Pavshook, 2007).

In addition, the USSR and Russians began research on a bimodal NRE, the Nuclear Power and Propulsion System (NPPS), which uses a closed coolant loop to produce energy either in addition to, or instead of, producing thrust. This system, based on the RD-0410, was tested during system development using H_2 , and plans were made for a He-Xe mixture gas generator for long term power generation (Wetch et al., 1991).

There are no currently active programs for a thermal NRE in Russia. However, the technology developed during the 1950s–1980s remains attractive to mission planners, and could be a strong candidate for modern designs (Zakirov and Pavshook, 2007).

Advanced nuclear thermal rockets

While the systems discussed so far have been tested to a greater or lesser extent, and are considered achievable in the relatively near term, there have been designs for more advanced nuclear thermal rockets since nearly the beginning of NTR development (Cooper, 1965). The thermal limitations of solid fuel forms were understood at the time, and the idea of using fuel that was not in a solid state offered many possibilities for increasing temperature and power density. *For more information on these types of NTRs, see the Advanced Propulsion chapter.*

Discussions of using liquid fuel rather than solid fuel were had in the US during the initial design phase of Project Rover, but were not pursued at the time (Schreiber, 1956). At least one concept, the Liquid Annular Reactor System (LARS), proposed by Dr. James Powell in 1991, used a uranium metal fuel element designed to partially liquefy along the propellant flow. The fuel would be retained using centrifugal force by spinning the fuel elements individually at a high rotational velocity (Powell et al., 1991). However, this general form of NTR has had very little development, either theoretical or experimental, even when compared to the other advanced NTR concepts.

The use of uranium hexafluoride as a fuel, contained within a cylinder and compressed by a piston to achieve the necessary density to achieve criticality, was discussed by Dr. Robert Bussard in his 1953 paper “Nuclear Energy for Rocket Propulsion” (Bussard, 1953). Work on this concept was conducted by the United Aircraft Corporation, under contract to NASA, from the mid-1960s until 1972 (McLafferty, 1969; Rogers, 1972). The primary focus of this program was to develop a vortex-stabilized fuel element able to be tested in the Nuclear Furnace (see above), but that program was canceled before testing could occur. On the other side of the world, Soviet designers had plans for an NRE fueled using uranium gas, and operated an experimental reactor from 1957 to 1970, although this was not configured as an NTR (Dmitrievskii et al., 1972).

In the US, open cycle gas (or plasma) core NTR design centered on NASA’s Lewis (now Glenn) Research Center (LRC) outside Cleveland, OH, starting in 1953 (Ragsdale, 1963). Experiments concerning all aspects of a gas core NTR were conducted from early 1960 through the mid-1970s at LRC, including hydrodynamics, neutronics, and thermal management (Jarvis et al., 1976). Due to the incredibly high temperatures (up to 10,000 degrees K), the lack of physical containment of the fissile fuel itself, and other requirements, this type of nuclear reactor is very difficult to build for any function (other uses are high powered fission-boosted lasers or actinide transmutation to reduce waste from nuclear power plants (NASA Jarvis et al., 1976)), but the challenges of an NTR are exceptionally difficult. Advances in computer power, thermo- and hydrodynamics, and computer modeling led to a resurgence in theoretical design calculations on plasma phase NTRs in the early 1990s (Poston and Kammash, 1994). However, due to the high cost and regulatory burden of conducting fission-powered tests of experimental reactor designs in the US, fission-powered testing of such a reactor has been incredibly rare, with only two test runs of bench-top experimental apparatus being conducted since the middle of the 1970s. Occasional theoretical work on this challenging concept continues to be done on an infrequent basis to the present day (Beveridge, 2016), but there have been no major programs of study on this type of system since.

The Soviet Union investigated the use of uranium microparticles in a similar system. Work on this concept began in 1954, by NPO Energomash and the Keldysh Center in Moscow. Various tests of neutronics, hydrodynamics, thermodynamics, materials, and other design challenges have continued to the present day, although the project has not had a high priority since 1975 (Koroteev and Son, 2007).

Due to the significant theoretical, computational, materials, and engineering challenges of developing these advanced NTR concepts, very little testing has been conducted, and much of the work conducted since the 1970s has been conducted either through graduate and PhD student studies, small-scale efforts within organizations, and other similarly scaled programs. They remain an attractive option to leverage the advantages of NTR propulsion, but as during Project Rover their challenges in design and testing prevent large-scale testing and development programs.

Conclusion

Nuclear thermal rockets as an engineering solution to the challenges of spaceflight have been around since the beginning of the nuclear age. Their development as a real-world system began with the space race in both the US and USSR, and both countries made significant progress towards flight-ready systems until their programs were canceled.

The challenges of NTR development, though, are huge. Not only do these systems require the nuclear reactor to be operating at as close to its operating limits as possible, but they also necessitate the use of certain types of materials and subsystems that at the time of the initial development push were only experimentally validated, not applied in the real world. New types of fuel elements, coolant/propellant systems, and other key components had to be designed and tested almost from scratch, with all the challenges of new complex engineering systems needing to be addressed.

NTR development has also been hindered by the lack of testing in the field, with fewer than 1000 hot-fire tests conducted in total, and none in the US since 1972. This is in contrast to chemical rocket engines, which are tested hundreds or thousands of times before they are used for a mission. Fully capturing the heated propellant, along with the fission products and any other material that was dislodged from the reactor during operation, is a significant engineering challenge for even a sub-scale system, such as the Nuclear Furnace, much less a fully integrated, full-size NTR.

The costs of developing an NTR are incredibly high. Not only does the reactor itself require specialized high-temperature materials for many of its components, but the power density of these systems is far higher than most other types of nuclear reactors as well. Finally, the testing equipment for an NTR, from initial component testing through full-scale hot firing is costly, complex, and must be incredibly robust in order to ensure that fission products and other radioactive materials aren't released into the environment (this was not the case in the initial Rover testing, but since then has become an absolute necessity).

More advanced NTR concepts, such as non-solid-phase fuel elements, pebble bed designs, and others, offer even greater benefits in terms of specific impulse, thrust-to-weight ratio, and power density, and as such have undergone their own programs of study and development. The challenges of thermodynamics, hydrodynamics, reactor stability, and other key characteristics may have kept them from becoming as well developed as the solid core NTRs, but programs in both the US and USSR have addressed many of the basic physics questions—although significant hurdles remain, and the development of these systems is still far longer term than a solid core NTR would be.

Despite these challenges, NTR systems offer unique capabilities for interplanetary missions, and as such have been an interesting mission planning tool for many mission concepts for the Moon, Mars and beyond. They remain an attractive option for deep space missions, and will remain so for the foreseeable future. As humanity continues to expand into the solar system, the benefits of NTR propulsion will continue to grow, and additional development will advance the NTR to flight-ready status, culminating in their much-delayed application in real world missions.

Introduction

The dream of Nuclear Thermal Propulsion (NTP) has been pursued off-and-on since the initiation of the Project Rover in 1955. Previous chapters in this encyclopedia discuss the challenges to successful NTP development (Poston, 2021a) and the history of past NTP programs (Graham, 2021). The Rover/NERVA programs made significant progress in developing a useful NTP technology, but unfortunately could not advance the technology to flight. After Rover/NERVA was ended in 1973, there have been several NTP programs, but none have even progressed to the building of a prototypic system, nor a system test. The lack of progress in NTP is not surprising given the large set of unique challenges discussed in the previous chapters. Especially since there has been almost no success in developing any new reactor technology over the past 50 years, even for systems much simpler than NTP. This article focuses on the potential technologies and testing approaches that might serve as options to mitigate these challenges, and perhaps ultimately result in the realization of NTP.

Note that NTP (Nuclear Thermal Propulsion) and NTR (Nuclear Thermal Rocket) can often be used interchangeably. The distinction in this article is that NTP typically encompasses the field/technology of nuclear thermal propulsion, and NTR refers to an individual nuclear thermal rocket.

Reactor configuration options

A “typical” NTR is referred to as a solid-core nuclear rocket. In a solid-core NTR, a propellant is heated as it flows through and cools a nuclear fission reactor, and is expanded through a nozzle to create thrust. There are numerous potential materials and geometries to create a solid-core NTR, and they are discussed below. All of the historical testing, and virtually all of the historical NTP research has involved solid-core NTRs.

In a solid-core NTR, the propellant outlet temperature (which is the primary metric of efficiency) is limited by the maximum material temperatures in the reactor core (generally between ~ 2500 and 3000 K). The attractiveness of NTP depends greatly on the propellant outlet temperature, which translates directly to specific impulse or I_{sp} (a measure of how effectively propellant is used ([Poston, 2021a](#))). This has lead others to consider higher performance concepts that could achieve substantially higher temperatures. The next level of performance (temperature) could be obtained by allowing the use of liquid fuel, although there would still need to be structural material that would limit the maximum temperature, perhaps in theory up to ~ 3500 K. An even higher temperature option is to operate the fuel as a gas/plasma. Various schemes have been developed to contain a very-high-temperature uranium plasma and prevent contact with reactor wall. In all these gas-core concepts hydrogen flows between the reactor vessel and the plasma. Containment options include a transparent silica barrier (a.k.a. nuclear-light-bulb), magnetic fields, hydrodynamic flows or vortices, or even the rocket acceleration itself. Most gas-core NTR concepts have theoretical propellant outlet temperatures of ~ 5000 – 6000 K, but there is no specific lower or upper limit. There are also many other nuclear rocket types but they would not fall under the NTR umbrella: e.g., fusion, antimatter, direct use of fission fragments, and even the detonation of small nuclear explosives. Further discussion of advanced propulsion concepts is provided in [Howe \(2021\)](#).

There is also the potential to create a reactor that creates both thermal-thrust and electrical power. This configuration is referred to as a bimodal NTR. Adding the requirement for longer-life electricity production on top of the already enormous difficulties of developing NTR, might make any pursuit of bimodal NTR concept premature. Another “hybrid” NTR approach utilizes chemical combustion to enhance the thrust of an NTR by combusting the exhaust with oxygen ([Borowski, 1994](#)). The liquid-oxygen-augmented NTR propulsion approach can give an NTR the ability to throttle to higher thrust (at the expense of I_{sp}) at times when it could benefit the mission profile.

Technology options for solid-core NTRs

The remainder of this article focuses on NTP technology options for “traditional” solid-core NTRs; although some of the technologies might be applicable to other NTP configurations or advanced reactors.

Fuel options

Rover (carbon-based) fuels

The fuels developed during the Rover program, and also tested as part of the NERVA program, are the only NTP fuels ever tested under prototypic conditions, and thus remain one of the options that must be considered for NTP. The term “Rover fuel” encompasses a large variety of different graphite-based or carbide fuels. All of the Rover fuel elements were prismatic (elongated hexagonal-shaped) elements that could be arranged in a triangular lattice pitch in the reactor core. These elements typically had 19 holes for hydrogen coolant (propellant) flow. [Fig. 1](#) shows a photo of a typical fuel element geometry.

The early years of the Rover program used UO_2 fuel particles embedded in a graphite (where the graphite is referred to as the matrix material). Later, the rather poor performance of the UO_2 fuel lead to a switch to UC_2 . The UC_2 particles were then coated with pyrolytic graphite (PyC) because UC_2 is very reactive with air/oxygen. The hydrogen flow channels were coated with NbC to prevent erosion due to graphite-hydrogen reactions. All of the NERVA rocket tests used this UC_2 fuel coated in PyC. As Rover/NERVA testing progressed they found that ZrC coating worked better as a liner than NbC and it became the baseline. Molybdenum was also tested as a liner material, but there was not enough data to draw a clear conclusion ([Finseth, 1991](#)).

Despite numerous tests, there was still a problem with fuel corrosion and fission-product release with the UC_2 /PyC fuel, even when lined with ZrC. This issue was believed to be caused by cracking in the ZrC, due to the difference in thermal expansion between graphite and ZrC, as well as significant vibrations of the fuel elements. Towards the end of the Rover program work began on new fuel forms that could be more robust in the high-temperature hydrogen environment. There was considerable success with a composite fuel where the graphite matrix existed among a network (veins) of U-Zr carbides ([Lyon, 1973](#)). Forms of graphite were used that matched the higher thermal expansion, and the resulting fuel was much more resistant to cracking or damage. Composite fuels were tested from 5 to 16 w/o (weight percent) uranium; the lower the U w/o the higher the potential operating fuel

Fig. 1 Photo of a Rover prismatic composite fuel element (Bhattacharyya, 2001).

temperature and vice versa (ranging from ~ 2500 to ~ 2800 K). **Fig. 2** shows a side-by-side depiction of the coated particle and composite fuels.

The final fuels tested in the Rover program were binary carbide fuels consisting of U and Zr carbides, where the fuel is mixed as a solid-solution, or effectively a homogeneous mix of different carbide fuel forms. These fuels have the capability to prevent significant carbon loss, as well as any cracking that would expose the graphite to the hydrogen, in addition they have the potential to operate at > 3000 K in NTRs. Unfortunately, this bi-carbide fuel form only received limited research and testing prior to the program's cancellation. **Fig. 3** shows the projected endurance of the Rover fuels as a function of the propellant exit temperature.

Since the completion of the Rover/NERVA programs there has been continued research on various type of carbide fuels (Pranda, 2005), and interest appears to be currently intensifying in 2020. There is also growing interest in other Rover-like fuels that might be of interest to NTRs and other reactor applications. There is ongoing research into other cercer fuels, which place a ceramic fuel (UO_2 , UN, UC) in a ceramic matrix (e.g., SiC, MgO). Technically Rover fuel is also a cercer (because graphite is considered a ceramic), but cercer fuel generally refers to the use of any ceramic material other than graphite. There is also ongoing research in to TRISO fuels (Helmreich, 2021), which is similar to the Rover coated-particle fuels except that there are three coatings surrounding the fuel kernels (referenced by the "TRI" in TRISO); these coatings make the fuel more robust to thermal expansion, fission product release, and damage during processing. TRISO fuel has great potential for reactors on Earth, mostly because of how they effectively preclude

Fig. 2 Schematic depictions of Rover coated particle and composite fuels (Koenig, 1986).

Fig. 3 The projected endurance of Rover fuels versus hydrogen exit temperature (Koenig, 1986).

the release of radioactive fission products, but TRISO appears unattractive for NTRs and other space reactors due to low uranium density (i.e., poor neutronics).

Cermet fuels

Cermet (ceramic-metallic) fuels utilize ceramic fissile particles embedded in a metallic matrix. The fuel fraction in a cermet fuel might range from 50 to 70 v/o (volume percent); a high fuel percent is desirable for better neutronics/mass, but higher fuel fraction leads to poorer fuel structural properties at high temperature. The metal matrix of cermet fuel provides strength at very high temperatures, as well as the strength to withstand significant loads that could occur under launch and re-entry accident conditions. The excellent thermal conductivity of the metal results in a low temperature difference between the fuel and the coolant gas, thus allowing high H_2 exit temperatures.

Most of the cermet fuel researched and tested in the US has been UO_2 fuel particles coated in W, then embedded in a W matrix. Typical elements have been shaped in the same prismatic form as the Rover fuel; i.e., hexagonal blocks with holes for the passage of gas coolant/propellant. The perimeter of the hex and the coolant channels were clad/lined with W-Re. This liner was intended to minimize chemical interactions between the hydrogen and the fuel. In addition, the various layers between the fuel and the H_2 propellant were meant to provide multiple barriers to fission product release during operation; this may be required to gain safety and public acceptance for both the ground testing and space flight phases.

Previously UO_2 cermet development programs have found that a small fraction of oxide stabilizer is needed to promote the chemical stability of the UO_2 : Gd_2O_3 was the most often used, which even a stronger neutron absorber than W. Cermet fuels could also use Mo, or a mixture of Mo-W, to facilitate easier fabrication and better neutronics (lower mass), but W should ultimately provide the best high-temperature performance. In addition, other ceramic fuels could be used to provide better neutronics than UO_2 , most notably UN, but it may have a lower temperature limit as well than UO_2 (due to nitrogen dissociation from the fuel at high temperatures). One possible approach to reduce mass is to use a Mo/UN cermet in the cooler inlet region and a W/ UO_2 cermet at the high temperature outlet region, although this would complicate development, plus the resulting power deposition shift to Mo/UN region diminishes the overall benefit.

The cermet fueled reactors are characterized by a hard/fast neutron energy spectrum under operating conditions. The presence of large amounts of tungsten and rhenium in the core make the core inherently safe under submersion conditions, because of the increased absorptions of neutrons in the thermalized spectrum of the submerged core. The fast spectrum is also preferable from a system dynamics and operational perspective (Poston, 2021a). These characteristics, plus the robustness of the fuel material as discussed above, appear to make the cermet fuel the best option for a typical NTP application from a performance perspective.

There are three primary difficulties associated with the use of cermet fuel. The first is the lack of reactor test experience, especially when compared to the wealth of experience for prior Rover fuels, although this disadvantage may disappear if proposed NTR concepts do not use fuels similar to those that were demonstrated (even then, it may be difficult to correctly recapture the technology). The second disadvantage is that cermet-fueled reactors may only be attractive if the fuel uses highly enriched uranium (HEU), due to the neutronic absorption of the refractory metals (although it is debatable if an attractive cermet reactor could be

Fig. 4 Various W/UO₂ fuel samples (Bhattacharyya, 2001).

successfully developed without HEU as well—all of the Rover/NERVA testing used HEU). The third hurdle to the use of cermet fuel is fabrication, which is especially difficult if the matrix material is tungsten. Fig. 4 shows some W/UO₂ cermet fuel samples; this type of fuel was fabricated by Argonne National Laboratory and the General Electric Company in the 1960s. More recent cermet fuel fabrication efforts have been conducted by Hickman (2012) and O'Brien and Jerred (2013). A historical review of cermet fuel development is provided in Stewart (2015).

Alternative fuel geometries

The aforementioned prismatic fuel form has been the most studied shape for fuel assemblies, and the only form tested in a NTR, but other options have been investigated that have potential advantages.

Wire fuel elements

Wire fuel is potentially attractive because it might be easier to fabricate than prismatic hexes, it provides excellent heat transfer to the propellant (via high surface area and low conduction thickness), and potentially a lower mass core. A study was conducted in the mid-60s by Atomics International of a compact, high performance nuclear rocket engine that employed tungsten wire fuel elements (Arnold, 1965). The wire was fabricated by filling a braided tungsten wire tube with 100 μm UN particles, vapor depositing tungsten onto the tube, and then mechanically forming and strengthening the wire (e.g., swaging, drawing, twisting, etc.). The core was to be constructed of layers of wire wound over alternate layers of spacer wires, which formed an annular lattice. The Soviet Union also pursued what they referred to a twisted-ribbon fuel, which was a carbide based fuel (Borowski, 1993) and is shown in Fig. 5. Although the theoretical performance of wire fuel is very good, the biggest drawback is ensuring the required flow distribution to adequately cool all sections of the fuel. Even a small mismatch between power and flow can be catastrophic in an NTR, due to the high power densities and low margins required to gain adequate performance. A wired-fuel concept might require numerous ground nuclear tests to determine whether power-flow mismatch can be avoided in all operational regimes.

Particle fuel elements

Particle fuel elements are designed with annular beds of small diameter ($< 1\text{ mm}$) fuel particles contained between two coaxial porous cylinders (frits); the frits effectively replace the matrix for containment of the fuel. The most significant efforts for a particle-bed NTR were conducted by Brookhaven National Laboratory (Powell, 1988) and later by the US Air Force in the SNTP program (Walton, 1993). In these concepts the propellant flows radially through the particle-fuel element from the cool outer frit to hot inner frit, and then the propellant exits axially towards the nozzle. The reactor core consists of particle fuel elements arranged in a hexagonal pattern, potentially surrounded by moderating material. The advantage of this design is generally easy fuel fabrication and high surface area per unit volume. Similar to a wire-fueled concept, the disadvantage is ensuring that flow is well distributed through the bed of particles. There is also the potential of particles clogging the holes

Fig. 5 Soviet twisted ribbon fuel (Bhattacharyya, 2001).

within the frits, and the difficulty of ensuring the structural integrity of the frits themselves. Therefore, this concept is also likely to require several system ground tests to determine if it is practical.

Pebble bed reactors

Pebble-bed reactors place the fuel in larger (several mm to cm) diameter round packages (pebbles). The fuel is typically comprised of small particles placed in a matrix of graphite or ZrC; thus it is a certer fuel in a different form than the prismatic hexes. The pebble is typically clad in a relatively thick layer of ZrC. Pebble bed NTRs have the advantage of larger and potentially more predictable flow gaps (as compared to particle fuel element concepts); however heat transfer to the H_2 is diminished by the larger thermal conduction path, potential thermal resistance between components, and a longer path for the hydrogen (which requires a larger pressure drop). The biggest problem with pebble bed reactors might be engineering and qualifying the core structure, which is discussed later. The use of pebble bed reactors for nuclear thermal propulsion is discussed in El-Genk et al. (1994).

Enrichment options

The safeguarding of special nuclear material represents a significant development and deployment risk to the HEU systems. The costs for security and potential infrastructure are substantial, and the use of HEU also involves political and bureaucratic risk. While HEU will present significant increases in cost and risk, it must be noted that an HEU system has recently been built and tested by NASA (i.e., KRUSTY (Poston, 2021b)); this shows that even in today's environment HEU fuel can be successfully fabricated, shipped across US and tested. The total amount of ^{235}U required might also be a discriminator. At present, the US has a large supply of HEU that could be used, but civilian applications will generally not be given high priority for its use, and there is also the risk that it will be down-blended for political reasons. However, if the need (and will) exists, additional uranium can be enriched with modest technical cost as compared to NTP development. Most concepts consider using either HEU (93% enr.) or HALEU (19.75% enr.), because the costs and policy issues generally remain high until the enrichment falls below 20%.

The most obvious advantage of using HEU is mass. For any given core type of geometry, HEU will offer a much lower mass option. The less obvious advantage of using HEU is simplicity. In many cases, LEU cannot provide a low-enough mass without the use of neutron moderation. The use of a neutron moderator adds several layers of complexity. The moderator technology must be developed and integrated into the core. The moderator also needs to operate at a much cooler temperature than the fuel, thus requiring an entirely separate cooling path to be plumbed into the system, and a very high effectiveness insulator to be developed/integrated that operates at extreme temperature in a potential H_2 environment. Perhaps the biggest risk of adding a moderator is that it greatly increases the complexity of system dynamics and operations, due to the addition of large, competing reactivity coefficients, and the potential for high reactivity worth of the moderator coolant (which is colder and higher pressure/density than other H_2 in the core). Overall, the use of LEU provides either a significant mass penalty or adds significant development risk. Given that NTP development is exceedingly difficult, and low-mass is highly desirable, it may be very unlikely that a useful LEU NTR could ever be developed.

Propellant options

Hydrogen is the choice for almost every NTR application. The key is the low molecular weight of H_2 , which allows the atoms to be accelerated faster per unit energy than any other atom or molecule. The key to efficient rocket propulsion is the exit velocity of the gas, and given the same rocket conditions (e.g., chamber temperature and pressure), H_2 will provide substantially more thrust per propellant mass expelled (specific impulse).

Unfortunately, the use of hydrogen comes with many complications that make it much harder to deal with than other propellants: One of the issues with H_2 is that it penetrates into and through most materials rather easily, more-so at elevated temperature. Hydrogen embrittlement is a concern for structural materials, and leakage through pipes, tanks, and other boundaries must be mitigated. Probably the biggest issue with using H_2 propellant is that it has to be stored cryogenically. The tank thickness to store a sufficient amount of gaseous H_2 at pressure, and without diffusion loss, would generally create an unacceptable mass penalty. Cryogenic storage of fuels is difficult, especially for the long anticipated trip times of human Mars missions, and even then a liquid H_2 still requires a rather large storage volume (due to low density). Hydrogen is also very erosive/corrosive, which presented a major problem during the Rover/NERVA programs. Lastly, hydrogen is a highly volatile substance, and can create significant safety issues associated with storage and transfer.

Carbon dioxide (CO_2) could provide an option for a return flight from a Mars mission. The propellant could be drawn and stored directly from the atmosphere, although the electrical power required to compress the very low-density atmosphere into a high-pressure tank would be substantial. Also, the CO_2 would dissociate at high temperature, into carbon monoxide and oxygen, and then to just carbon and oxygen. This would introduce many potential materials issues within the reactor that would have to be mitigated. Methane (CH_4) would be a possibility for the mission to Titan. Methane dissociates into carbon and hydrogen, which will provide materials issues, but it does have the advantage of storing more efficiently than CO_2 or H_2 . However, if methane is available, it might be more efficient to try and use it as a conventional rocket combustion propellant than as an NTR propellant, provided that an oxidizer could also be provided. Ammonia (NH_3) is another alternative that could be attractive. It has a low molecular weight and dissociates into nitrogen and hydrogen, which is likely better from a materials and specific impulse perspective. Also, ammonia is commonly used in space today, so it comes with a lot of technology heritage. If supplies of ammonia can be found on asteroids or outer planets, it might be the “in situ” propellant of choice, or it could also be made by a chemical plant if the infrastructure existed.

Structural options

The ability to keep the core and reactor intact provides a unique challenge to NTP development; because of extreme temperatures, temperature gradients, pressures, flow velocities, and vibrations (during launch and operation). Regardless of the structural approach, it might be expected that numerous structural failures would occur during initial system testing, as is often the case during traditional chemical rocket deployment. Structural problems were clearly a significant problem during the Rover/NERVA program. The NRX test series of the NERVA program had 16 significant structural failures and anomalies that occurred over the 6 ground test design iterations, including cracking, flaring, rubbing, breaking of various components (Koenig, 1986). Fortunately, the repeated test and fail cycles did ultimately lead to a successful demonstration of core structure, via tie rods and tie tubes.

Tie-rods

The majority of the Rover tests and all of the NERVA tests used what were referred to as support-rods or tie-rods. Tie-rods were used to support the prismatic fuel elements, which were unable to provide mechanical support to themselves. The tie-rod used a metal tube (typically Inconel) to support an array of six surrounding fuel elements as shown in Fig. 6. In order to maintain strength and integrity, the tie-rods were required to be cooled by diverting some of the H_2 flow along the length of the rod. This approach worked very well, but there were a few difficulties. First, if there was a sudden shutdown and loss of flow, the heat transfer from the fuel sometimes overheated the tie-rod and caused a failure. This problem is unavoidable to some extent if the core support must operate at a lower temperature than the fuel. The second issue of using a tie-rod is in rocket performance; the low-temperature flow that cools the tie-rod is ejected into the rocket plenum, and therefore decreases the bulk coolant temperature, and thus thrust and specific impulse. The final Rover test, Pewee, placed a sleeve of ZrH moderator around the tie-rod to moderate the reactor, which allowed a smaller core, and reduced fuel and core mass (Koenig, 1986).

Tie-tubes

A tie-tube is a modification of a tie-rod which eliminates the performance penalty of ejecting the low-temperature flow into the rocket plenum. Instead of a simple 1-pass flow geometry, a 2-pass flow geometry is used, where flow proceeds down the tube from the inlet, reverses in a plenum, and proceeds back up to the inlet region where it is remixed with the flow to proceed through the fuel. This allows all of the flow to be heated to high-temperature by the fuel, although it significantly complicates flow plumbing and requires the turbopump to create higher pressures to create the tie-tube flow. The only Rover/NERVA test that used tie-tubes was the Phoebus 2A test (Fig. 7), and the tubes reportedly worked well (Koenig, 1986). Subsequent tie-tube concepts have been proposed to incorporate a moderating material inside of the tie-tube, but that was never tested (that option will be discussed below).

Fig. 6 Rover fuel assembly using tie (support) rod (Koenig, 1986).

Fig. 7 Tie-tubes used for the Phoebus 2A Rover test.

High temperature structure

The strategy that was successfully deployed by the Rover/NERVA program was to employ a sub-cooled reactor structure (i.e., the structural material was maintained at a lower temperature than the primary coolant outlet temperature). The drawback of this method is the diversion of flow, and the necessary plumbing to cool the structure, and the potential failure of the structure due to loss of flow (which led to damage in some tests). Other NTP concepts have considered using high temperature core support, which eliminates the aforementioned problems, but introduces other substantial engineering challenges. The biggest challenge is the ability for the structure to perform adequately at the coolant outlet temperature (typically 2500–3000 K); this is made even more difficult by the difficulty of testing the proposed structure without a prototypic nuclear-powered ground test. Also, the best candidate structural material at these temperatures might be tungsten, but it is difficult to fabricate, is very brittle, and is a strong neutron absorber.

Cermet-fueled reactors offer the opportunity to use high temperature structure because the cermet fuel, and potential cladding, may have the ability to support themselves. The fuel elements can be supported at the cold end similar to tie-tubes, and potentially other high-temperature structure surrounding or at the bottom of the core. Some previous cermet NTR concepts have progressed to the point of creating a structural design and it does appear feasible (Argonne National Laboratory, 1966); Fig. 8 shows the fuel element design for the Argonne concept.

The other application that could use a high temperature structure for core support would be a pebble-bed reactor, which would use frits to hold the entire core together, as opposed to a particle fuel element where the frits are part of smaller fuel elements. A typical pebble-bed NTR is shown in Fig. 9, and a discussion of the thermal-hydraulic issues presented by a pebble-bed NTR can be found in (Morley and El-Genk, 1994). The frit must contain the entire core at the H_2 outlet temperature, survive the intense thermal stress/strain of a high power NTR, and also allow enough flow area to prevent excessive pressure drop. The engineering and development of this core structure presents an enormous engineering challenge, and would almost certainly require repeated nuclear-powered ground testing to succeed.

Fig. 8 Design drawing of cermet NTR fuel element (dimensions in inches).

Fig. 9 Drawing of a pebble bed NTR (El-Genk et al., 1994).

Moderator options

One of the primary performance metrics of NTP is mass, and moderation is generally the most effective option to reduce mass (all other design parameters being equal). Carbon-based fuels offer some moderation, as well as the H₂ propellant itself, but increased moderation can be obtained by interspersing additional moderating material throughout the core. On Earth, large high-temperature reactors often utilize graphite as additional moderator, but the small size required for NTP does not allow additional graphite to be

effective. In general, hydrogen is the only effective moderator, because it thermalizes neutrons much more efficiently per collision than any other element (because it is effectively the same mass as a neutron).

Moderator material

The most attractive candidate material for external moderation is likely ZrH. Zirconium-hydride can operate at relatively high temperatures (~ 900 K) and provide a high hydrogen ratio, generally ranging from 1.6 to 2.0H/Zr ratio. The biggest technology risk associated with ZrH is hydrogen loss, which could reduce reactivity and potentially prevent criticality. The higher the hydrogen ratio, the lower the operating temperature needs to be to prevent hydrogen loss. In most applications, cladding, liners, or coatings are used to prevent significant hydrogen loss.

An NTR has the potential to cool ZrH to very low temperatures (< 400 K) such that hydrogen loss would not even be an issue. Also, the short operating times of an NTR (hours) can allow a relatively high loss rate. Unfortunately, the hydrogen loss rate increases exponentially with temperature, such that if the ZrH reaches > 1000 K the H can be lost in a matter of minutes (depending on hydrogen ratio and the types/thickness of coating used). In addition, it may not be possible to keep the ZrH as cold as desired because of the need to remove power deposited in the ZrH, and more importantly the spillage heat from adjacent fuel elements. "Spillage" represents the heat flow from the very-hot fuel to the very-cold moderator coolant. In most scenarios the predicted power from spillage is much higher than the power deposited in the ZrH, because it is difficult to fit sufficient insulation between the fuel and the moderator coolant channel. This added power makes it difficult to limit the moderator coolant temperature rise from inlet to outlet. Also, the uncertainty in insulation performance under prototypic conditions will make it very hard to predict spillage, so that considerable design margin will be needed to prevent ZrH exceeding its upper temperature limit (again, depending on the hydrogen ratio and types/thickness of the coatings used). The extreme temperature swings in an NTR, specifically during startup, will also create significant opportunity for the coating to crack. The overheating failures that occurred with the Rover/NERVA tie-rods due to loss-of-flow will be even harder to prevent, given that ZrH will require lower temperatures than an Inconel tie-rod. All of these issues make the use of ZrH risky, because of the additional constraints it imposes on NTR design. The Pewee test took the simple approach by diverting sufficient excess H_2 flow to ensure ZrH cooling, but this approach will not yield sufficiently attractive NTR performance.

Another potential moderator is YH, which does not provide as much neutronic benefit as ZrH, but has a higher temperature limit, which could provide more margin for the aforementioned thermal design challenges. Conversely, LiH (enriched in ^7Li) would provide even better neutronic benefit than ZrH, but has an even lower temperature limit. Note that "neutronic benefit" refers to lower fuel mass, not necessarily easier development, because added moderation creates other significant complications, and will be discussed below. Other hydrogenous materials like water, polypropylene, etc. are generally unattractive because they require even colder temperatures. Graphite could potentially be used, but as mentioned above it is relatively ineffective in the small geometries required for space reactors. Beryllium is a possibility, even though it is considered more of a reflector material (high scatter) than a moderator material (large atomic mass difference versus hydrogen), but given its very low neutronic absorption it can work fairly well as a moderator if the region is thick enough. Some potential NTR configurations (e.g., the use of a moderator block) might be able to provide enough physical space to effectively use Be or BeO as a moderator. There is also the potential to use lower-temperature fuels in low temperature regions to boost reactivity and thus reduce mass; however, this is likely to amplify the aforementioned power removal issue such that it would not be practical.

Moderated tie-tubes

A moderated tie-tube is an idea to place moderator in the potential empty space in a Rover/NERVA tie tube, in order to reduce the required fuel mass. Although moderated tie-tubes were never built or tested, the idea is based on the successful heritage of moderated tie-rods and unmoderated tie-tubes. In the Pewee test, a small annulus of ZrH moderator was placed around the tie-rods, but was still cooled by single-pass flow diverted from the primary flow. In the tie-tubes of Phoebus 2A, the hydrogen flow moved down through the central rod/tube, and was returned to the core inlet via a counter-flow annular tube. The moderated tie-tube would fill the region between the down-flow tube and counter-flow annulus with a relatively low temperature moderator (likely ZrH) to aid in neutronics. Fig. 10 shows the proposed tie-tube design for the Small Nuclear Rocket Engine (SNRE) concept (Durham, 1972), which was created shortly after the end of Rover/NERVA testing.

The difficulties of using a moderated tie-tube are mostly associated with thermal management. The power deposited in the moderator has to be removed, as well as the power "spillage" (leakage heat transfer) from the fuel assemblies to the tie-tube. A layer of ZrC insulation is intended to prevent spillage, but it will be hard to verify the magnitude of heat transfer. Also, the density of hydrogen in the tie-tube is much higher than in the core (it is at higher pressure and colder temperature than the thrust fuel elements), which creates the potential for significant reactivity changes caused by changes in H_2 flow conditions.

Moderator block/monolith

A monolithic structure can also provide a low-temperature location for a moderator, or the monolith could be the moderator itself, if ZrH, Be, or BeO could provide reliable structural support. Alternatively, a stainless-steel block could hold ZrH pieces, or a very

Fig. 10 NERVA derived moderated tie-tube (Fittje and Buehrle, 2006).

high performance system could use a beryllium block to hold ZrH pieces. In all cases the block would need to be cooled by a low-temperature flow stream separate from the fuel.

The Soviet NTR program reportedly pursued the use of a ZrH block, in which carbide-based fuels were interspersed; however there is very little public technical information about this program, so it's difficult to know if they made any significant progress or perform a nuclear-powered system test of this concept. However, the use of a ZrH block with axial holes that contained fuel elements was ground tested in the TOPAZ-II reactor program (Voss, 1993). The configuration was different than for an NTR, in that the block and fuel (thermionic fuel elements) used the same cooling stream and the block had significantly different structural requirements, but the test effectively demonstrated the viability of a moderator block system. Recent efforts by NASA are also considering a moderator block, either using BeO or ZrH (Houts, 2018). As for the tie tubes, the biggest issue of a moderator block might be predicting the heat spillage from the fuel to the moderator, which must be known rather precisely to provide enough power to the turbopump while not overheating the moderator. The primary advantages of using a moderator block instead of moderated tie-tubes is the ability to include more moderator (which allows lower mass) and the reduction of local power-peaking factors (due to a more symmetrical moderating effect). The disadvantages of a moderator block will be ensuring the structural function of the block and the plumbing of the coolant flow, and the potentially larger reactivity feedback caused by increased moderation.

No moderator

Apart from mass, the best option for any NTP concept is to not use a moderator (other than inherent carbon that might be part of the fuel or structure). The use of a moderator creates many technical risks: (1) an additional material/technology is used in the reactor, which must be developed and qualified for NTR conditions. (2) The core geometry must allow the inclusion of the moderator and allow mechanical integration. (3) The nominal neutron spectrum of a moderated reactor does not generally allow the use of intrinsic launch safety. (4) The smaller neutronic worth of the radial reflector of a moderated reactor can make ground, transport, and launch safety harder to address. (5) Thermal management of the moderator becomes an additional design constraint, plus other design limits/requirements that the moderator might impose. (6) The low maximum temperature of the moderator increases the potential for irrecoverable core damage during reduced flow scenarios. (7) A separate coolant flow stream must be provided to cool the moderator. (8) A moderated reactor is generally much more sensitive to impurities or as-built material specs, as well as unknown or uncertain reactivity effects. (9) The reactivity of a metal-hydride-moderated system can be very sensitive to the hydrogen/metal ratio maintained by the hydride material, with detrimental operational and dynamic effects if hydrogen deviates a few percent from the design value, or hydrogen is lost or redistributed during operation. (10) Moderation will almost always substantially increase the magnitude of reactivity feedback coefficients, which makes operation and transient response more uncertain. (11) Moderation will almost always move the reactor neutron spectrum into regimes where nuclear data is more uncertain (e.g., epithermal versus fast), plus the added neutronic uncertainty of the moderator in the first place. (12) The moderator temperature can be very uncertain because of less certain power density distribution across the core, potential heat transfer from hotter regions, and a less certain heat rejection path, in particular, if a high level of insulation is required. (13) A moderated reactor often

result in more than one strong reactivity feedback component, which can conflict with each other depending on power and temperature, create various possible zero-reactivity state points, and create instabilities. (14) The higher magnitude and uncertainty of feedback (as well as more uncertain thermal performance) of a moderated system will tend to require more reliance on robust instrumentation and a flexible, fast-acting autonomous control system. (15) The combination of #7 through #14 makes performance and system dynamics extremely hard to predict, and in general make the moderated option more reliant on nuclear-powered ground testing than a similar, higher-mass system with no moderation (or a smaller amount of moderation).

Point #15 can easily become a showstopper without a ground test infrastructure to perform design, build, and test iterations. In general, it would be preferable to avoid the use of a moderator if possible, and even then, perhaps not until the 2nd or 3rd generation of NTP systems, where the development risk might be reduced to a level which could justify the pursuit of lower mass.

Despite the above generalities, it is unwise to make a blanket statement about the pros and cons of moderation. The same is true when selecting fuel form, or any other NTP design/technology option, because every application is unique. The comparisons and trades need to be made for a specific set of assumptions and requirements. An example trade study can be found in [Poston \(2018a,b\)](#).

Turbopump power options

High-thrust, high-Isp NTRs require high volumetric flow rates and high pressure drops; because flow area is limited by criticality and high velocity is needed to reduce film temperature drop (temperature drop between the cooled surface and the coolant). This combination of high flow and pressure drop requires considerable pumping power. A turbopump ([Chen, 2006](#)) is usually considered the best pumping option, except for extremely low-thrust systems where an electric pump, tank pressure, or other options might work.

For very low-thrust NTRs (< 44.5 kN (10 klbf) of thrust) the pumping power can sometimes be gained via what might be considered a traditional expander cycle. At thrusts $\gg 44.5$ kN the only practical way to get this pumping power is to utilize power from the reactor core, potentially by a hot-bleed or topping cycle.

Expander cycle

The expander cycle is often used in chemical rockets. In this cycle, the cold propellant is used to cool the chamber, nozzle, and other components, and the enthalpy gained by the fluid is then used to drive the turbopump. An NTR will have a considerable amount of regenerative heat from the nozzle because of the extremely high propellant temperature. Also, a good fraction (several percent) of the reactor power is deposited outside of the core, primarily in the radial reflector and shield regions. The cooling of these regions can also contribute to the regenerative heat that powers the turbopump, provided that these components are plumbed upstream of the turbine (note that this heat is not technically regenerative, but it best describes it in the context of standard rocket terminology).

For low thrust options (< 44.5 kN) it may be possible to gain enough turbine power from these regenerative sources, although startup will be complicated by the differing nature of these two power sources. The regenerative power from the nozzle is proportional to the system temperature (driven by the temperature gradient from the hot propellant), while reflector/shield power is proportional to core power (power deposition from neutron and gamma flux). Therefore, the availability of these power sources will depend on the power/temperature profile of the startup.

Hot-bleed cycle

A hot-bleed cycle extracts hot gas from the thrust chamber (core exit plenum) or nozzle (upstream of the nozzle constriction); this was the technique used for NERVA testing, and as such has an existing NTR heritage. A hot-bleed cycle introduces technology issues and can significantly hurt performance. The bleed inlet/piping, where the very-hot gas from the thrust chamber is extracted, has to be transpiration-cooled (injection of cold gas through the wall), unless extremely high temperature piping/turbine can be used; this reduces the bulk fluid temperature via mixing. After powering the turbine, the relatively low-temperature hydrogen must be discharged at a low specific impulse. In addition to the design complexities, this can lower ISP by > 50 s ([Koenig, 1986](#)), a huge penalty for any propulsion system. The NERVA documentation recognized that the hot-bleed cycle was not preferable for performance, but indicates that hot-bleed was selected because it was deemed simpler than attempting to extract turbine power from the core (e.g., topping or driver cycles, which are described next).

Topping cycle

In a chemical topping cycle, a pre-burner is used to provide additional power to the flow prior to entering the turbine. A nuclear topping cycle instead routes coolant flow through the reactor core to gain enthalpy prior to reaching the turbine. The topping flow stream can utilize the entire reactor flow rate or a fraction it, and can be in series or parallel with the expander (regenerative) flow stream.

Tie-tube flow

Tie-tubes have been the proposed option to provide turbopump power in most NTP concepts that have been generated since the completion of Rover/NERVA testing. Instead of exhausting the tie-rod flow into the chamber, which will reduce the bulk temperature and I_{sp} , the flow is returned to provide enthalpy to the turbine. In a moderated system, there is significant power deposition in the moderator as it slows down neutrons. The bigger source of power to the tie-tube flow is the unwanted heat spillage from the fuel to the tie-tube; unwanted because it hurts rocket performance. The spillage effectively causes the peak fuel power density to occur at higher coolant temperature, which reduces the rated power and/or I_{sp} . The heat spillage also presents significant operational and performance difficulties, although in some cases the extra spillage power is beneficial to reach the desired turbine power.

Core block/monolith flow

Some NTR concepts propose the use of a monolithic block structure to support the fuel and provide a cool environment for a moderator. In this case, the topping flow could be gained by cooling the block. The direction of the flow would depend on the balance of structural, material, and thermal issues. Flow in the same direction as the thrust flow might help reduce unwanted heat transfer from the fuel to the block, ease the insulation burden in the chamber region, and mitigate thermal expansion stresses. Flow counter to the thrust flow direction might simplify the plumbing/routing of the flow stream, by routing the nozzle regeneration cooling directly to the bottom of the core. In either case, providing a flow plenum/piping to the extremely hot chamber region might present significant engineering challenges.

Driver fuel flow

The tie-tube and core-block flow options above are “benefits” of a moderated NTR concept, in that the cooling is required regardless, so it might as well be put to good use. Alternatively, an unmoderated NTR has the advantage of not requiring a highly-subcooled core region, but is left with the challenge of cooling a fueled region to power the turbine.

If an unmoderated NTR requires more pump power than can be provided by regenerative cooling, it will have to designate certain fuel regions or elements to power or “drive” the turbine (Poston, 2014). Driver fuel elements could be designed to heat the topping flow to the optimal temperature for the turbine. The lower outlet temperature of the driver coolant flow (versus the thrust flow, i.e., the flow from fuel elements that exhaust into the thrust chamber) would allow fewer, larger flow channels than a thrust element (while still adequately cooling the fuel). A smaller number of larger flow channels improves neutronics (lower coating fraction) and more importantly can allow a relatively low pressure drop.

Three in-core options for driver fuel are discussed below. It might be possible to place driver fuel outside of the core, for example as part of the radial reflector, but that might introduce unwanted issues with power balance, insulation, flow routing, and system dynamics.

Perimeter driver elements

The most attractive position for driver fuel elements might be on the core perimeter. The elements could be designed for 2-pass flow (inner down-flow and outer counter-flow like tie-tubes) or flow could return in the slat/structural region outside of the core. Perimeter driver fuel allows relatively simple plenum design and more flexibility for insulation. The biggest advantage of perimeter driver elements is that they essentially eliminate a big potential reactor design issue—power peaking in the perimeter fuel. The low coolant temperature can allow for the potentially large temperature gradients that might be created by edge power peaking (i.e., the localized peaking around the perimeter of the core due to the return of moderated neutrons from the reflector).

Internal driver elements

These elements would be 2-pass elements very similar in function to moderated tie-tubes, but use fuel instead of moderator and could operate at a higher temperature. They would use a plenum structure similar to that proposed for tie-tubes and potentially provide core structural support if the thrust elements pose structural difficulties. The difficulties of internal driver fuel elements might be differential thermal expansion (from the thrust elements) and the potential for too much heat transfer (spillage) from the thrust elements to the driver elements without significant insulation.

Inlet driver elements

These elements would be short elements placed at the core inlet. The best option might be a 3-path element, which would allow passage of the primary core coolant through a large central hole (low pressure drop and heat transfer), with internal flow channels cooling the fuel, and driver flow returning around the element exterior. Inlet driver elements would have the ability to take advantage of the entire core area (lower pressure drop) and would not have differential axial expansion concerns. The biggest challenge of inlet driver elements would likely be the complex plumbing; also, the inlet region has a relatively low flux/power, so more fuel volume would have to be allocated to driver fuel.

Testing options

The ability to ultimately perform a successful rocket test is the largest obstacle facing NTR development. The performance conditions of an NTR (e.g., temperature, power density, coolant volatility) are far more challenging than any reactor ever successfully deployed in human history. Fuel development, structural performance, safeguards, and launch safety are all major obstacles, but the ability to create the infrastructure (money, facilities, people) to test, get the approvals to test, and design/engineer a system that actually works is the biggest hurdle.

The need for testing is highly dependent on the NTR concept selection. It is important to design the system to be as simple as possible in terms of system dynamics and controllability, so that testing can be closer to a demonstration than an actual test. The option for in-space testing (i.e., flight testing) may be very attractive for NTRs; although if this option is pursued, then it is even more important to avoid operational complexity and uncertainty; i.e., it needs to be even closer to a flight demonstration than a test. Another approach is to construct a facility that guarantees containment for all credible core dispersion scenarios, but qualifying this facility might be harder than qualifying the NTR itself.

Ground test facility

During the Rover/NERVA programs 19 different NTR reactors/engines were tested at the Nevada Test Site (NTS), now designated as the Nevada National Security Site (NNSS). These tests were conducted in open air as shown in [Fig. 11](#). There were no reported radiological health issues associated with the testing, and even after serious reactor accidents they were able to successfully cleanup the test areas for subsequent testing. New regulations appear to make this type of testing impossible, such that the exhaust from an NTR would not be allowed to directly enter the atmosphere. This issue was starting to be addressed by the Rover/NERVA program in the early 1970s, when they demonstrated a scrubbing system that prevented the majority of radioactive particulates and noble gasses from being released into the open air.

Several options for scrubbing and condensing NTP exhaust have been proposed. The basic approach used by Rover/NERVA is described in [Gerrish \(2014\)](#):

The system cooled the hot hydrogen exhaust from the engine with a water spray before entering a particle filter. The exhaust then passed through a series of heat exchangers and water separators to help remove water from the exhaust and further reduce the exhaust temperatures. The exhaust was next prepared for the charcoal trap by passing through a dryer and effluent cooler to bring exhaust temperatures close to liquid nitrogen. At those low temperatures, most of the noble gasses (e.g., Xe and Kr made from fission products) get captured in the charcoal trap. The filtered hydrogen is finally passed through a flare stack and released to the air.

Fig. 11 NTR testing at the Nevada Test Site.

Fig. 12 Volumetric flowrate of gas generated by an NTR (1 cfm = 28.3 L per minute, 1 klbf = 4.45 kN).

The sheer volume of gas produced per minute by an NTR makes scrubbing difficult; volumetric flow rates are shown in [Fig. 12](#) ([Bulman, 2011](#)). Also, because an NTR can melt within seconds if coolant flow is lost, the scrubbing system might have to be able to filter the entire core inventory as well.

Bore-hole or underground testing

It is unclear if a facility could ever be built and qualified to capture NTR effluents and potential core dispersion within a realistic cost and schedule. This has led people to consider testing alternatives that use holes in the ground (either tunnels or boreholes) to capture and filter exhaust. The most attractive location might be at the NNSS, the same location as the Rover/NERVA testing. This is also the same location as the proposed spent nuclear fuel facility at Yucca Mountain, which is very remote and the prevailing rock (Alluvium) is well suited to inhibit the spread of actinides and fission products. [Fig. 13](#) shows a schematic of the SAFE

Fig. 13 Schematic of the SAFE borehole testing concept.

(Subsurface Active Filtration of Exhaust) borehole testing concept (Howe et al., 2001). Another option is to test in tunnels deep within the ground, many of which also exist at the NNSS (Borowski, 2016).

Approvals for testing

For a US NTP effort, the ability to get government approval to test is a major risk (whether via NRC or DOE). NTRs have very small temperature margins and extremely high power densities, which are far beyond any other successfully deployed reactor (certainly far beyond the scope of any potential regulator). Average adiabatic heat-up rates range from ~ 500 to ~ 2000 K/s depending on the concept. These values are 25–100 times higher than a typical PWR, and higher still than a typical BWR. The implication is that if cooling is lost during powered operation, each of the proposed NTR cores would melt within seconds. Decay power is also a significant concern; 1 h after shutdown the adiabatic heat-up rate can still be > 1 K/s. NTR safety concerns, compounded by a high volume of combustible hydrogen, are well beyond any reactor safety approval that has been attempted in decades. During the recent DUFF (Demonstration Using Flattop Fissions) and KRUSTY (Kilopower Reactor Using Stirling TechnologY) reactor projects (McClure et al., 2020), DOE regulators were focused on the confidence, or lack thereof, in system dynamics and the potential to melt fuel. This will create a circular dilemma for NTR systems with complex, unknown reactor dynamics and control issues; i.e., these issues can only become known via nuclear system testing, while without in-hand solutions to these issues, there may be no ability to get approval for and successfully execute the tests. In light of this, the best, and perhaps only hope of getting regulator approval for testing is to make the NTR as predictable, simple, and safe as it practically can be.

Space flight test or demonstration

Given the difficulties of ground testing of NTRs, the other option is to develop an NTR via flight testing/demonstrations. A possible flight development path would likely be composed of several increasingly difficult flight demonstrations. The initial demonstrations would require systems with very simple performance and dynamic behavior, because of the limitations of diagnostics to both operate the system and subsequently learn from failures, as well as a limited supply of onboard H_2 (which will not be sufficient to spend hours starting up and exploring the operating space as was done during Rover/NERVA tests). Systems that have strong/complex reactivity feedback, high hydrogen reactivity worth, low tolerance to heat transfer uncertainties, etc. might never be successful via flight development, or at a minimum require numerous flight tests/demonstrations. Alternatively, if a NTR could be pursued that has simple dynamics, (e.g., an HEU cermet-fueled system), then success might be achieved with only a few evolutionary steps.

The most important feature of a flight demonstration (FD) system is that the performance is well-understood and predictable. For a first-of-a-kind flight demonstration simplicity of operation is imperative because of uncertainties in thermal and neutronic behavior, and most importantly because of limited system diagnostics in space. Establishing the reliability and accuracy of diagnostics is extremely difficult in nuclear reactors, and an NTR will have radiation fluxes and temperatures that far exceed those in any existing reactor. Therefore there will be great uncertainty regarding the readings of any instrumentation. In-core temperature measurements may not be possible at all, which would present a major problem for any system that has complex reactivity feedback, including large moderator reactivity feedback coefficients.

For a first flight demonstration it will be nearly impossible to design and develop an advanced automated control system, i.e., one that can determine which instruments to “believe,” what can be actually inferred from their readings, and then decide what actions to take. The use of an NTR with simple and predictable operation is needed if for no other reason but to learn how well diagnostic information can be measured and processed. A system that requires complex control (real time control of reactivity and pump/valves) is not only likely to fail for lack of poor diagnostics, but more-so will not allow a determination of which diagnostics are performing adequately in the first place (because performance would be largely unknown). In that case, very little would be learned from the first or any flight demonstration—which is why a system with significant uncertainties and/or complex dynamics should be developed via ground testing, or evolve gradually from simpler systems.

The US Defense Advanced Research Projects Agency (DARPA) is actively pursuing an NTP flight demonstration program (Greiner, 2020). NASA also recently investigated the potential for a very simple flight system, referred to as Flight Demonstration One (FD1) (Poston et al., 2019), but it was not pursued further.

Ground development or flight development?

As indicated above, the development of NTRs, via ground or flight provides a major challenge; which presents a difficult choice for present and future NTP programs.

Ground testing is clearly the most likely approach to succeed technically, because of the complexity of NTRs. The path to success would probably require numerous design, build, test, iterations to succeed, as evidenced by the need for 19 different ground test campaigns during the Rover/NERVA program, after which they gradually learned how to design, test, and operate the system (and it likely would have taken many more to achieve success). The ground development path would require a massive investment in testing infrastructure and government support at the highest levels to sustain the program. Then, even if the aforementioned can be obtained and sustained over multiple executive administrations, there is still a risk of not getting ultimate approvals to test, or getting into a “Yucca Mountain” paradigm (i.e., not getting final permission to use the facility after it is ready to start being used).

Flight testing is clearly the lower cost of the two options, since a fully-qualified NTR test facility would likely cost $> \$10\text{B}$; based on a comparison to the cost of other DOE facilities that have had much simpler requirements. Borehole or underground testing would be initially lower cost, but the overall cost would depend on how many separate tests were needed. However, as discussed above, it will be very difficult to learn and evolve a technology as difficult as NTP in space. Perhaps the only option would be to test/demonstrate very simple concepts initially, to develop techniques for testing in space, as well as develop NTP technologies.

There is no simple answer to this testing dilemma. Many years after the completion of Rover/NERVA, some of the most experienced and respected NTR engineers weighed in on the side of ground testing, as evidenced by the quoted text below (Bohl, 1990):

The 17 years of experience in the ROVER/NERVA program clearly demonstrated that invaluable results are always obtained from testing these systems—either in the form of verification of successful designs, or by identifying problem areas. Furthermore, such results are not mutually exclusive, as components of marginal design can be “smoked out” while others perform without a hitch in the same test. Even without need for further concept development, it would be imprudent to launch a flight engine on an interplanetary mission with no prior attempt to demonstrate that the integral system could satisfy all of its performance requirements—and, that no component performs marginally. The amount of instrumentation required for the latter confirmation may be prohibitive on a flight vehicle.

Launch safety options

Launch safety for a space reactor is unique when compared to all other space technologies. Even if fully dispersed, an un-operated uranium-fueled reactor does not pose a realistic radiological threat to personnel or the public. The only credible nuclear risk is inadvertent criticality of the reactor. Preventing criticality during water immersion is very difficult for NTRs, due to their relatively large diameter (less radial reflector/drum worth), large coolant area, and difficulty of integrating internal safety rod(s).

Some cermet reactor concepts can use the preferred method for launch safety; i.e., they can be inherently designed to remain subcritical upon water immersion (i.e., there is no “safety” system). The use of this option depends on the fraction of W, Re and/or Mo, the radial reflector reactivity worth, and the core flow area (which can be reduced at the expense of higher pressure drop). In most cermet concepts, the W and Re in the fuel and liners serve as spectral poisons; i.e., they absorb far more neutrons in the moderated neutron spectrum during water immersion than they do in the nominal fast spectrum state.

To achieve subcriticality during water immersion a cermet and/or moderated concepts might utilize neutron-poison wires (gadolinium, borated material, etc.) within the flow holes of the centermost fuel elements. These wires would extend through the nozzle and be removed in a controlled fashion after the system had launched and the probability of reentry is adequately low. The “perfect” bundle size (tight-packed triangular pitch) would have to be substantially less than the nozzle area because tangling will be inevitable. Also, the greater the tug angle (i.e., the angle at which the wire is pulled relative to its axial direction in the core), the greater the chance for loads that could jam/break wires and/or damage the fuel-coating, orifice, or nozzle surfaces.

The engineering of a potential wire-safety system (with perhaps 1000–4000 wires) presents great technical challenge: inserting the wires into the coolant holes, bundling them neatly into the pull mechanism, the design and integration of the mechanism with the nozzle (where attached, how held structurally, how ejected). The greatest difficulty might be designing and proving that the mechanisms (and individual wires) will stay in place during impact while also allowing reliable withdrawal and ejection after launch. If a single wire is not fully withdrawn (breaks off or gets stuck), it will almost certainly result in mission failure unless the reactor is designed with excessive thermal-hydraulic margin. A concept that requires hex and individual flow channel orificing could also be impacted, by not allowing any orificing at the core exit. The testing of the wire system will have to be extensive—enduring launch and impact loads, as well as simulating wire withdrawal in micro-gravity environment (thus effecting how the wires might tangle).

There is some heritage for a wire-safety system. During the Rover program a system was used to place wires in several holes during transport, although, apparently it only used wires that could be drawn straight out (not at an angle) and the system was not designed for launch loads or possible impact loads. There are other possible techniques to prevent inadvertent criticality, but they do not appear promising. Explosive dispersal could be used but will be tough to prove and extremely harder to “sell” (and may not be preferred for safeguards for an HEU system). Methods could be developed to prevent water ingress in the core (removable containment, fast acting foam, etc.), but these types of system seem impractical.

An NTP concept could also attempt to use safety rods which could be withdrawn into the region above the core, into the shield space and potentially beyond. Integration would present the major problem in this case; the biggest consideration would be whether the rods are inside the pressure boundary or not.

The final option for launch accident safety is to allow criticality in water immersion, and prove that it does not represent a consequential risk to the public. This is an acceptable option and almost certainly is technically credible. The difficulty will come in how concrete the technical argument must be. The fully-flooded k_{eff} of some NTP systems can be > 1.1 ; if this level of neutron multiplication was actually achieved the results would be catastrophic. Fortunately, there is no credible possibility that any NTP system could approach these levels, in fact it may even be unlikely that any sort of prompt reactivity insertion would occur (depending on the rate of water ingress). Regardless, the hypothetical prompt reactivity insertion accidents will certainly be questioned and have to be evaluated. There is also another programmatic risk of this approach; i.e., in addition to having to satisfy review boards that it is ok if the reactor goes critical during water immersion. A decision-maker might be wary of allowing a system to launch that would go critical if it fell in the ocean, because of the way it would likely be treated in the media; even if it posed no real danger.

Summary

NTP provides the most substantial challenges of any fission reactor ever conceived, given the extreme conditions presented by temperature, power-density, rapid startup, corrosive coolant, etc., plus the need to operate remotely and reliably in space. If not for the amazing accomplishments of the Rover/NERVA program the idea of NTP might appear far fetched. Fortunately, the successes of Rover/NERVA, although far from achieving flight, gives hope that a useful NTR could be developed. The key will be to find the simplest path to getting a first generation NTR in space. Of the technologies presented in this article, the HEU-cermet NTR might have the best chance for success. Unfortunately simple often competes with other priorities. For example, an HEU NTR would be dramatically simpler than an LEU NTR, but policy concerns might prevent the use of HEU. Similarly, an 700 s I_{sp} NTR would be dramatically simpler, lower-cost, and more likely to succeed than a 900 s I_{sp} NTR, but some potential customers would not want to pay for what would be considered the first step in the evolution of NTP. Even then, a realistic 700 s I_{sp} NTR program might take more time and funding to succeed than most present-day customers would be willing to sustain. The advantages of NTP are compelling, but will likely only be realized by taking relatively simple incremental steps.

Introduction

Liquid and solid rockets have dominated the space propulsion field since before the space race of the 1960s. However, in the last decade electric space propulsion systems have been developed that can revolutionize the way we travel through the solar system. These propulsion systems are 10–100 times more efficient in their use of propellant than traditional rocket engines. These electric propulsion systems are well developed and have sailed across the solar system traveling to distant locations such as asteroids and the moon (Levchenko et al., 2018).

While these electric propulsion systems are incredibly efficient with their propellant, these systems require electrical power to operate. So far, missions have used solar panels providing kilowatts of power. However, if the power source were able to provide the engines with megawatts of power without significantly increasing the mass of the system, then rapid transportation around the solar system would be possible.

A nuclear fission reactor is one type of system that could feasibly provide megawatts of power while maintaining a relatively low mass. Nuclear fission systems have been used before in spacecraft to provide electrical power to spacecraft components, but they have not been used to power a propulsion system (Buden, 2011a). Over the last two decades electric propulsion has now demonstrated a clear application for megawatt-scale nuclear electric power systems. NASA's *Technology Roadmap for Space Power and Energy Storage* states this about space fission technology:

Fission provides ‘game-changing’ solutions for powering advanced NASA missions. Game-changing attributes of space fission systems include virtually unlimited fuel energy density, the ability to operate independent of solar proximity or orientation, and the ability to design for operation in extremely hostile environments (e.g., high dust, high radiation, or high temperature). Fission can enable a power-rich environment anywhere in the solar system. (Lyons et al., 2010, p. 12)

Why is electric propulsion any better than any other propulsion technology? On Earth electric propulsion is useless because it needs a vacuum to work. But once in the vacuum of space, it can revolutionize the way we travel around in our solar system neighborhood. To sum it up in one thought: electric propulsion is the most fuel-efficient form of propulsion that changes the paradigm from a capsule strapped on top of a skyscraper of fuel to a comfortable spacecraft filled with tools and supplies with a small propellant tank.

The importance of “ ΔV ”

Sometimes space is thought of as a place that lacks gravity. However, in reality all objects in space are bound by gravity. Satellites orbit the Earth because they are stuck in Earth's gravity well. The Earth orbits the sun for the reason.

ΔV can be thought of as the final speed of a rocket as it travels through space. Traditionally it is measured in km/s. A rocket starting at rest will have a final velocity equal to its ΔV if there are no other forces acting on the rocket. Gravity is a force that is acting on the rocket. If a rocket wants to travel from one point to another, the rocket must overcome the difference in gravitational energy between the two points. This difference is overcome with ΔV (also known as delta-v).

When traveling in a car on Earth, the trip is measured in miles. In space, a trip is measured in ΔV . A mission to Mars, the Moon, or another star all have different ΔV requirements. Just like a car needs more gas to overcome air resistance at high speeds, a rocket requires more ΔV to travel to its destination very quickly. ΔV by itself isn't enough to describe everything just like looking at a car's odometer can't tell you how fast the car went, but ΔV is a place to start.

The rocket equation

In the field of space propulsion there is one fundamental equation that applies to all forms of propulsion that use propellant. It is called the rocket equation. The rocket equation determines how ΔV for a spacecraft.

$$\Delta V = V_{\text{exit}} \ln \left(\frac{m_{\text{spacecraft}} + m_{\text{propellant}}}{m_{\text{spacecraft}}} \right) \quad \text{The Rocket Equation} \quad (1)$$

Where ΔV is the total change in velocity, V_{exit} is the exit velocity of the propellant from the rocket nozzle. Looking at this equation, there are three ways to increase the ΔV . One way is to increase the ΔV is to add more propellant. Another way is to decrease the mass of the spacecraft. Neither of these options are attractive.

Liquid and solid rockets typically have a propellant mass fraction of around 90%. For example, the Space Shuttle's final mass on orbit was 6.5% of the initial launch pad mass meaning the 93.5% of the shuttle was propellant and staging. Increasing the mass fraction helps achieve high ΔV , but greatly reduces the payload that can be delivered.

The third and best way to increase the ΔV is to increase the exit velocity of the propellant. The increase in ΔV is proportional to the increase in exit velocity. The table below describes the exit velocity values for generic liquid, solid, and electric engines.

The exit velocity for electric engines is one to two orders of magnitude higher than the exit velocity of the solid or liquid propellants. This means that electric engines are approximately 1–100 times more efficient with their fuel than traditional liquid or solid engines. In other words, an electric powered rocket could complete a mission with 1–100 times more ΔV as compared to a similarly sized chemical rocket. This gain for electric propulsion is reduced by the “Orbith Effect” (which will be talked about in a later section of the document), but still leaves electric propulsion as a propellant efficient form of propulsion.

Nuclear thermal rockets are like chemical rockets except instead of using combustion to increase the exit velocity of the rocket, they flow their propellant through a reactor core. Nuclear thermal rockets have been ground demonstrated in the 1960 and 1970s NERVA/ROVER program that achieve double the exit velocity of liquid rockets make them twice as fuel efficient as liquid systems (Buden, 2011c). A few more advanced nuclear rockets technologies using liquid core, gas core, fission fragment and or nuclear light-bulb technologies can achieve exit velocities levels in the range of 10–15 km/s.

There are several types of electric engines, but their basic function is to take an electric power source and excite a propellant to very high speeds and temperature. Most electric engines (also known as thrusters) use electromagnetic fields to contain and accelerate the high temperature propellant allowing the propellant to achieve extreme temperatures without melting the structure of the rocket. Electric propulsion systems are varied and deserve more discussion, but in general to achieve exit velocities close to the speed of light and practical systems have.

A commonly used measure of exit velocity is called the specific impulse or I_{sp} . Specific impulse is proportional to the exit velocity and is measured in seconds.

$$I_{\text{sp}} = \frac{V_{\text{exit}}}{g_{\text{sea level}}} \quad \text{Isp Relationship} \quad (2)$$

Where $g_{\text{sea level}}$ is equal to Earth's acceleration due to gravity at sea level which is equal to a constant 9.81 m/s^2 . For example, the I_{sp} of a 3 km/s exit velocity is approximately 300 s. I_{sp} is a standard unit used in industry to describe the performance of rocket engines.

The propulsion systems in Table 1 are systems that could be used in inter-solar travel. Traditionally rockets delivering a payload in the Solar System use their bottom stages to get into orbit around Earth and then use their upper stage to propel a rocket stage into the Solar System. Table 2 details the upper stages of several chemical launch rather than the lower stages for this reason.

Table 1 Exit velocity of different types of propulsion.

	<i>Solid</i>	<i>Liquid</i>	<i>Nuclear thermal</i>	<i>Electric^a</i>
Exit velocity (km/s)	2–3	2.5–4.5	8–15	10–>300

^aSeveral types of electric thrusters span this range, see Table 9.

Table 2 I_{sp} of various rockets for LEO to mars travel.

<i>System</i>	<i>Type</i>	I_{sp} (s)
SLS Block II EDS	Liquid (O ₂ /H ₂)	448
Falcon Heavy 2nd Stage	Liquid (RP1/O ₂)	342
Delta III/IV CDSS	Liquid (O ₂ /H ₂)	462
Atlas V second stage XX1	Liquid (O ₂ /H ₂)	451
Ariane 5 ECA	Liquid (O ₂ /H ₂)	446
NERVA	Nuclear thermal	900
Hall Thruster (Smart 1)	Electric (ES)	1000–1600
ITR (Hayabusa)	Electric (ES)	3000
NEXIS (JIMO)	Electric (ES)	6000–7500
NEXT (Dawn DS1)	Electric (ES)	3100
VASIMR (VX-200)	Electric (EM)	2000–30,000

ES: Electrostatic; EM: Electromagnetic.

Liquid engines have an upper limit around 450 s. A few advanced liquid technologies using fluorine and beryllium can achieve an I_{sp} in the 500 s range. Solid core nuclear thermal engines could achieve an I_{sp} as high as 1000 s. Electric engines shown have all been lab tested. Many of them have been flow in deep space missions. Electric propulsion has a wide range of I_{sp} from 100 s to approximately 30,000 s or even higher depending on the design.

Staging, gravity loss, and drag

The rocket equation can express the theoretical ΔV of a rocket. However, knowing the ΔV of a rocket alone cannot give us all the information required to plan a trip into the Solar System. The solar system can be thought of as a “interplanetary superhighway” system. Sometimes shortcuts can be taken reducing the required ΔV just like a car could take a shortcut over a toll road. Some types of propulsion systems can’t take certain routes on the highway similar to how semi-trucks aren’t allowed on certain bridges. Different propulsion systems will require different ΔV . It’s important to understand the differences in order to make a valid comparison between electric propulsion systems to other types of propulsion.

Staging

Rockets typically are split into stages that separate the propellant into tanks that can be dropped before the next stage is ignited. This improves the ΔV of the rocket by around 20–35% depending on several factors including the payload mass, fuel mass, and fuel tank mass. Rockets rarely use more than three stages because each additional stage offers less benefit. Chemical propulsion benefits most from staging because the fuel tanks are very large. Electric propulsion can utilize stages, but the propellant needs are greatly reduced, and the benefit of staging is reduced. However, a single stage electric propulsion system is easier to reuse as there are less “pieces” to logistically track. A single stage propulsion system is like a car which has a gas tank that can be refilled.

Planetary positions and gravity assists

The planets are constantly moving around the Sun and missions only become practical when planets are aligned. Sometime this occurs on a regular basis such as when Mars and Earth are lined up every 2.1 years. Sometimes much rarer events occur such as Voyager II’s use of the gravity from Jupiter, Saturn, Uranus and Neptune to ultimately escape from the Solar System. Gravity assists fly the spacecraft closely in front or behind a planet to use the gravity to accelerate or decelerate the spacecraft. Based on the alignment of the planets, it can take long periods of time to traverse the circuitous routes between planets. The Voyager probes used a rare planetary configuration that which enabled the probes to visit multiple planets, picking up excess velocity along the way to escape the Solar System faster than any other human made object (Fig. 1).

Atmospheric drag

Atmospheric drag increases the ΔV required if a spacecraft is attempting to leave a planet, but it can drastically decrease the ΔV required for a mission if the spacecraft is attempting to slow down to either orbit or land on a planet. On Mars the atmosphere is thick enough that a technique known as aerobraking can be used. Instead of using the rocket’s ΔV to slow down to enter orbit,

Fig. 1 Voyager II gravity assists (Doody and Matousek, 2020).

the rocket can be flown close enough to Mars to allow the atmospheric drag to help slow the spacecraft and “aerobreak” reducing much of its excess speed. The ability of a rocket to use aerobraking is dependent upon its ability to withstand high temperatures and dynamic pressure from the atmosphere. All forms of propulsion should be able to utilize aerobraking if designed to be structurally capable and in some cases a spacecraft could deliver a smaller payload to a planetary body by detaching the payload and utilizing aerobraking.

Orbith effect/gravity loss—High acceleration vs. low acceleration propulsion

When a spacecraft is traveling through space there are locations where high thrust/acceleration is more efficient than other locations; typically, in locations in an orbit such as the apogee where the velocity of the spacecraft is greatest. Chemical and nuclear thermal rockets can achieve high acceleration for short periods of time. They can minimize their gravity loss by quickly utilizing their propellant in those locations. Electric propulsion provides low thrust but for very long periods of time. Electric propulsion typically requires 20–100% more ΔV compared to the high acceleration propulsion depending on the type of maneuver (for example by using perigee kick maneuvers can reduce the loss significantly but requires more time). Roughly for electric propulsion there is a 20–50% loss in effective ΔV .

Average velocity matching—When transit time matters

While ΔV determines if a mission can be accomplished, it doesn’t specify the amount of time it takes to complete a mission. A first estimate of time matching can be made using a kinematics that estimates the average velocity. If a propulsion system is high thrust typically it can be assumed that it can instantaneously increase and decrease the velocity. For an object wanting to travel a certain distance, the average velocity is equal to the total ΔV as it takes little to no time to accelerate to full speed. For a low thrust, continuously accelerating mission, the spacecraft requires time to accelerate to the maximum speed. The average velocity in this case is one half the total ΔV . Electric propulsion missions that are time constrained require around twice the ΔV of similar missions using high thrust propulsion to effectively match the average velocity. This is particularly challenging in deep gravity wells such as in near Earth orbit where the spacecraft doesn’t travel very far while taking many days to spiral out of the gravity well. For missions to distant locations, for example to the outer planets, it is less of an issue as the spacecraft will build up relative velocity as the gravity well of the sun is much smaller. Some electric propulsion engines can vary their I_{sp} . In the case of variable I_{sp} and constant power, the I_{sp} is reduced in gravity wells which will increase the thrust to accelerate the spacecraft at the beginning of a mission leaving earth and then the I_{sp} is raised and thrust lowered as the spacecraft reaches a greater relative speed. Another method to reduce the time penalty is to look at hybrid high thrust (chemical or nuclear thermal) and low thrust/electric propulsion missions. This strategy can be very effective in certain scenarios.

General propulsion system comparison

Considering all the effects mentioned above, it is difficult to directly compare the ΔV of high thrust and low thrust propulsion types. However, a general approximation can be made that can allow for a very broad comparison of different propulsion systems taking into account the effects above.

Assume that three spacecraft were developed, one chemical, one nuclear thermal, and another electric. Each one has the same total mass and propellant mass. Armed with general knowledge from the preceding sections, a first-look comparison can be made between the three different propulsion systems.

Looking at [Table 3](#) a general comparison of chemical nuclear and electric propulsion fuel efficiency can be made. Electric propulsion can be less fuel efficient compared to chemical and nuclear thermal at relatively low I_{sp} . However, higher I_{sp} is clearly capable of greater propellant efficiency and superior performance of electric propulsion. [Table 3](#) is a general first-order comparison of different propulsion system. Electric propulsion systems can require up to four times more ΔV to achieve a similar level of performance to high thrust propulsion. Despite this disadvantage, electric propulsion can achieve an I_{sp} well over four times that of high thrust propulsion systems to overcome this loss. Electric propulsion systems with on the order of 3000 s of I_{sp} and above start to yield an advantage over high thrust propulsion.

Space environment and humans—Higher ΔV and mass requirements

The conjunction mission to Mars is one of the lowest and repeatable ΔV maneuvers to get to Mars. The NASA DRA document ([Chang-Díaz et al., 2013](#)) describes the conjunction mission as a 2.1 year long mission with 380 days spent traveling through space and 539 days on Mars. For astronauts in space for 2.1 years in space is taxing.

Spending 2.1 years in space is hazardous to astronaut's health for several reasons. First because of the microgravity environment bone and muscle atrophy is very serious. The psychological impact is also not trivial. The native space environment is moderately radioactive. Very high energy protons from outside the solar system easily penetrate aluminum spacecraft shielding. Solar events such as flares pose the risk of causing radiation sickness in astronauts and damaging spacecraft. The radiation dose to astronauts on a 380-day round trip to Mars is around 55 rem ([Chang-Díaz et al., 2013](#)). That is approximately 10 times the maximum yearly occupational dose for radiation workers and 100 times the average yearly dose for Americans. Two ways to reduce the exposure to radiation is to travel through deep space quickly or to travel with more radiation shielding. Traveling more quickly requires significantly more ΔV , and more shielding typically requiring more propellant and larger spacecraft.

Electric propulsion and the importance of power and thrust

Electric engines have been well developed over the last decade and are much more efficient with their fuel as compared to the traditional chemical rocket. However, they have one major drawback they require a power source.

The rocket equation describes the amount of ΔV (total change in velocity) a rocket can achieve. How long does it take to achieve the ΔV ? The time required is inversely proportional to the power source. Rapid transportation is not possible without a low mass, robust power source. Eq. (3) describes the relationship between power and time.

$$t = \frac{m_{propellant} V_{exit}^2}{2P_{jet}} \quad \text{Power Relation} \quad (3)$$

P_{jet} is the jet power or the power delivered to the propellant, t is the time to achieve ΔV , and $m_{propellant}$ is the total mass of the propellant on board the spacecraft. Note that the jet power is less than the power generated from the power source because the power generated by the power source cannot all be used in the jet because of inefficiency such as heat dissipation. Eq. (4) below describes the relationship between jet power and the power source.

$$P_{jet} = \eta_{engine} \quad \text{Jet Power and Power} \quad (4)$$

Where η_{engine} is the efficiency of the propulsion system in transferring energy from the power source ($P_{power\ source}$) into the propellant jet in the spacecraft direction of travel (P_{jet}). Thrust is defined as:

$$T = mV_e = m I_{sp} g_0 \quad \text{Thrust Relationship} \quad (5)$$

Where T is thrust, m is the mass flow rate per unit time, and V_e is the exit velocity. Jet power is defined as:

$$P_{jet} = \frac{mV_e^2}{2} \quad \text{Jet Power Relationship} \quad (6)$$

Assuming a constant power source, we can increase I_{sp} at the expense of thrust. [Fig. 2](#) below describes the relationship between I_{sp} and thrust for a constant 1 MW of power.

Table 3 Comparable fuel efficiency.

	<i>Chemical</i>	<i>Nuclear thermal</i>	<i>Electric</i>
Exit velocity	4.5 km/s	10 km/s	10–300 km/s
Staging effect	135%	135%	100%
Orbeth effect	100%	100%	50–80%
Average velocity match	100%	100%	50–100%
Comparative propellant efficiency	6.0 km/s (600 s)	13.5 km/s (1350 s)	2.5–240 km/s (250–24,000 s)

Fig. 2 Thrust vs. specific impulse for a constant 1 MW power source.

Electric systems are revolutionary because they can reach very high specific impulses; however, to reach those specific impulses, a cost is paid in lower thrust. To develop a spacecraft that can transport cargo, a high Isp is needed. To transport cargo rapidly, a high thrust is needed. Therefore, to achieve rapid transportation, a strong power source is needed to complement the electric propulsion system.

The importance of specific power and specific mass

Higher I_{sp} allows spacecraft to transport more cargo and higher thrust allows for spacecraft to get to the destination faster. The available power limits the amount of thrust and I_{sp} that can be obtained. So, it is logical to think that maximizing power is the most important aspect for spacecraft. However, there is another piece of the puzzle, specific power. Specific power is a measure of the spacecraft's power per unit mass. The specific power of the spacecraft is defined as the total power of the spacecraft divided by the mass of the spacecraft without the propellant.

$$\bar{P}_{sc} = \frac{P_{jet}}{m_{sc}} \quad \text{Specific Power} \quad (7)$$

Where $\bar{P}_{sc}$ is the specific power in W/kg, P_{jet} is the power delivered to the propellant directional jet, and m_{sc} is the mass of the spacecraft without propellant. Let's reanalyze the situation by writing the rocket equation in terms of specific power (Table 4):

$$\Delta V = \sqrt{2E} \ln \left(1 + \frac{\bar{P}_{sc} m_p}{P_{jet}} \right) \quad \text{Electric Power Rocket Equation} \quad (8)$$

Where P_{jet} is the directional jet power of the spacecraft in Watts, $\bar{P}_{sc}$ is the specific power in W/kg, m_p is the propellant mass in kg, and E is the energy density imparted per unit mass on the propellant measured in J/kg. Looking at the average acceleration of the spacecraft in terms of the specific power (Table 5):

$$\bar{a} = \frac{\sqrt{2} P_{jet} \ln \left(1 + \bar{P}_{sc} m_p / P_{jet} \right)}{\sqrt{E} m_p} \quad \text{Average Acceleration} \quad (9)$$

Where $\bar{a}$ is the average acceleration of the spacecraft while it is achieving its ΔV . These two equations (Eqs. 8 and 9) are the fundamental equations that govern space travel. ΔV tells what missions can be accomplished, and $\bar{a}$ tells how fast those missions can be

Table 4 Specific power rocket equation derivation.

$\Delta V = V_e \ln \left(\frac{m_o}{m_f} \right)$	The rocket equation
$\Delta V = V_e \ln \left(\frac{m_{sc} + m_p}{m_{sc}} \right)$	Initial mass of the rocket is composed of the spacecraft mass and the propellant mass.
$\Delta V = \sqrt{2P_{jet} \frac{m}{\dot{m}}} \ln \left(\frac{m_{sc} + m_p}{m_{sc}} \right)$	$m_o = m_{sc} + m_p$ The exit velocity can be expressed as a function of power and mass flow rate.
$\Delta V = \sqrt{2P_{jet} \frac{m}{\dot{m}}} \ln \left(\frac{P_{jet}/\bar{P}_{sc} + m_p}{P_{jet}/\bar{P}_{sc}} \right)$	$V_e = \sqrt{2P_{sc} \frac{m}{\dot{m}}}$ Using the Eq. (7) $m_{sc} = P_{jet}/\bar{P}_{sc}$
$\Delta V = \sqrt{2P_{jet} \frac{m}{\dot{m}}} \ln \left(\frac{P_{jet} + \bar{P}_{sc} m_p}{\bar{P}_{sc}} \right)$	Multiply the specific power to the numerator.
$\Delta V = \sqrt{\frac{2P_{jet}}{E}} \ln \left(\frac{P_{jet} + \bar{P}_{sc} m_p}{P_{jet}} \right)$	The mass flow rate is proportional to power and inversely proportional to the energy imparted per unit mass. For example, twice the power means twice the propellant used. $m = P_{jet}/E$

Table 5 Power acceleration derivation.

$\bar{a} = \frac{\Delta V}{\Delta t}$	Average acceleration can be defined as change in velocity divided by change in time
$\bar{a} = \frac{\sqrt{2E} \ln \left(1 + \bar{P}_{sc} m_p / P_{jet} \right)}{m_p / m}$	Change in velocity was taken from Eq. (8) and change in time can be found by $\Delta V = m_p / m$
$\bar{a} = \frac{\sqrt{2E} \ln \left(1 + \bar{P}_{sc} m_p / P_{jet} \right)}{E m_p / P_{jet}}$	$m = P_{jet}/E$

Table 6 Specific power rocket equation dependencies.

Variable	$\bar{a}$		ΔV	
	Effect on $\bar{a}$	Dependence	Effect on ΔV	Dependence
E	Propellant energy density	↓	↑	$\sqrt{E}$
m_p	Propellant mass	↓	↑	$\ln \left(1 + \frac{\bar{P}_{sc} m_p}{P_{jet}} \right)$
P_{jet}	Power	↑ asymptotic	↓	$\ln \left(1 + \frac{\bar{P}_{sc} m_p}{P_{jet}} \right)$
$\bar{P}_{sc}$	Specific power	↑	↑	$\ln \left(1 + \frac{\bar{P}_{sc} m_p}{P_{jet}} \right)$

accomplished. Both equations are based on the same four independent variables. Table 6 below describes the relationship of these two equations against their independent variables.

Specific power is the dominant factor in electric propulsion. The three variables have mixed results on ΔV and $\bar{a}$. Increasing the propellant mass increases ΔV , but decreases $\bar{a}$. Similarly, E has the same problem. Increasing power has an asymptotic effect on ΔV . Specific power is the only variable that has a positive effect on both the ΔV and $\bar{a}$. Therefore, *specific power is the most important variable to maximize in electric propulsion spacecraft*. The other three variables can be balanced based against the requirements for the ΔV and time frame of the specific mission, but in general the performance of an electric propulsion system is limited by the specific power.

To define potential power sources, a better description of the spacecraft is needed. So far, a limited description of a spacecraft has been given that includes propellant (m_p) and everything else (m_{sc}). The masses can be further broken down in Fig. 3.

Fig. 3 Spacecraft mass breakdown.

Fig. 4 Conjunction class missions.

$$\alpha_{sc} = \frac{m_{sc}}{P_{jet}} = \frac{1}{P_{sc}} = \frac{m_{payload} + m_{power\ source} + m_{tanks} + m_{structure} + m_{engine}}{P_{jet}} \quad \text{Spacecraft Specific Mass} \quad (10)$$

Where α_{sc} is the specific mass and is measured in kg/W. Smaller values of α_{sc} are better. The specific mass can be defined as a sum of each of the component specific jet masses.

$$\begin{aligned} \alpha_{sc} &= \frac{1}{P_{jet}} \sum m_{component} = \sum \alpha_{component_{jet}} \\ &= \alpha_{payload_{jet}} + \alpha_{tanks_{jet}} + \dots \quad \text{Spacecraft Jet Specific Mass Expressed as Sum of Component Specific Mass} \end{aligned} \quad (11)$$

The specific mass of the spacecraft is mission dependent. For example, the payload can change from mission to mission and it is not useful to compare the performance of the propulsion system with two missions with different payloads. To better compare propulsion systems, it is useful to look only at the power source and engine specific mass.

$$\alpha_{PPS_{jet}} = \frac{m_{power\ source} + m_{engine}}{P_{jet}} = \alpha_{power\ source_{jet}} + \alpha_{engine_{jet}} \quad \text{Preliminary Payload, Power, and Propulsion System Specific Power} \quad (12)$$

The power and propulsion system are the key components of an electric propulsion system by which performance can be compared. Maximizing the propulsion system's specific power is the best approach to increasing the specific power of any spacecraft which utilizes electric propulsion. A fundamental question comes into play, what is a competitive specific power? Is there a way to find out what a competitive specific mass is regarding other propulsion technologies?

Conjunction class round trips to Mars

There are many different approaches to getting to Mars. Typically, the lowest ΔV approach which is regularly available is known as a conjunction class mission. A conjunction class mission regularly occurs approximately every 2 years when Earth and Mars line up. **Fig. 4** graphically depicts conjunction class mission.

Earth is green, Mars is red, the Sun is yellow, and the path of the rocket is in purple. The conjunction class mission begins with a transfer from Earth to Mars. The rocket must stay on Mars until the planets again line up for a transfer. The overall mission takes over 2 years due to the timeframe of the planets aligning. NASA and other organizations have put a lot of research into characterizing the conjunction class mission to Mars. **Fig. 5** below summarizes the results from NASA's conjunction class mission analysis in the Human Exploration of Mars Design Reference Architecture 5.0 over the 2030–2046 timeline.

All missions begin in 440 km circular low Earth orbit (LEO). There are three different maneuvers. First is the trans-Mars insertion (TMI) which takes around 200 days to propel the rocket from Earth toward Mars. Second is the Mars orbital insertion (MOI) that puts the rocket in orbit around Mars (250 km perigee and 33,793 km apogee). The rocket stays in orbit while the crew spends over 500 days on Mars. Finally, the trans-Earth injection (TEI) propels the rocket home from Mars (**Table 7**). The NASA DRA 5.0 contains analysis for both a chemical and nuclear thermal mission to Mars using the ΔV shown in **Fig. 5** for the near-term worst-case year 2037. The results of the nuclear thermal and chemical design process are shown in **Fig. 7**.

Fig. 5 High thrust conjunction class mission ΔV from NASA DRA v5.0 July 2009 Pg. 23 (Drake, 2009).

Table 7 NASA Mars design reference architecture 5.0-2037 Mars mission 374 transit days.

	Chemical	Nuclear thermal
Initial mass low Earth orbit	486.0	356.4
Stages	4	1 (plus one drop tank)
Payload (metric tons)	51.9 (10.7%)	62.8 (17.6%)
Fuel mass (metric tons)	347.6 Liquid H_2/O_2 (71.5%)	202.7 Liquid H_2 (56.9%)

What about electric propulsion? What would an electric propulsion spacecraft look like that has similar capabilities to the NASA Design Reference Architecture? A study was published by Ilin in 2013 that analyzed similar missions using nuclear electric propulsion (Chang-Díaz et al., 2013). The mission utilized the same starting location, initial mass, and payload assumptions as the NASA DRA 5.0 missions looking at nuclear thermal propulsion and can also be compared to the chemical propulsion DRA 5.0 mission as Fig. 6 gives the results from Ilin's work.

Ilin's work looked at several different $\alpha_{PPS_{jet}}$. This figure was made by using the data from his research which used the VASIMR engine and back calculating the specific mass of the power and propulsion system and verified in correspondences with the author including rerunning the calculations for 2037 rather than 2035. On the y-axis the in-flight days to and from Mars is shown. A $\alpha_{PPS_{jet}}$ of approximately 20 kg/kW_{jet} was able to reach the 374 days transit time for the conjunction class mission. This corresponds to a jet power of around 5.6 MW. The payload for the mission was 60 metric tons and the system started in low Earth orbit with an initial mass of 356 metric tons. By matching the payload and the number of days to and from Mars for the nuclear thermal propulsion the nuclear thermal and electric propulsion systems are objectively equivalent. Table 8 below summarizes the nuclear electric mission by Ilin and the DRA missions for chemical and nuclear thermal propulsion.

In the table you can see that in general the three missions are matched well in terms of the days to Mars and for the nuclear thermal and nuclear electric missions the payload is approximately equal. The specific impulse for the three systems varies significantly between all three with the electric propulsion having an average specific impulse approximately an order of magnitude higher. The ΔV for the missions is the same for chemical and nuclear thermal propulsion but almost four times higher for the electric propulsion mission. Some of this is due to gravity losses, however most of the extra ΔV required for electric propulsion is required due to excess ΔV for average velocity matching.

Fig. 7 brightly depicts the differences between the three propulsion systems. The percent of the rocket required as propellant is the important distinction. In the case of chemical, 71.5% is required as propellant shown as the red portion of the top bar. Nuclear thermal does much better with 59.6%, however electric propulsion is reducing the propellant to 46.6% of the rocket required as propellant. The green portion of the bar represents the payload. The black portion is the mass of the rocket that is neither propellant not payload. For the four-stage chemical propulsion system the black would represent the mass of the fuel tanks and the rocket engines and turbomachinery associated with the stages. The black portion of the nuclear thermal rocket would also represent the fuel tanks and engine. For the electric propulsion system, the mass of the tanks and power and propulsion system is explicitly shown. The electric propulsion's reduced need for propellant looks great, however there is one caveat. Unlike the other two propulsion systems it requires an electric power source.

What exactly is the "power source?" Chemical propulsion systems do not need a power source because the propellant provides the power for the rocket. Nuclear thermal rockets require a reactor as a power source to heat the propellant. The benefit of nuclear thermal propulsion is that the reactor power source can be provided by thermal energy. Electric propulsion on the other hand

Fig. 6 Jet specific power, power, and flight time for a 2037 flight to Mars using VASIMR with 70% electric power to jet power efficiency, and a 62 Metric Ton Payload (Chang-Díaz et al., 2013).

Table 8 Summary of NASA DRA 5.0 chemical and nuclear thermal propulsion missions.

	<i>Chemical</i>	<i>Nuclear thermal</i>	<i>Nuclear electric</i>
In flight days	374	374	370
Mission type	Conjunction	Conjunction	Conjunction
Initial mass low earth orbit	486.0	356.4	365.4
Payload (metric tons)	51.9	62.8	62.0
Specific impulse (s)	450	950	Average 4644
Year	2037	2037	2037
ΔV (km/s)	7.25	7.25	30.2
Tankage mass fraction	10%	10%	10%
Stages/tanks	4 stage	Single stage with jettison tanks	Single stage with jettison tanks
Propellant	H ₂ /O ₂	H ₂	Argon
Starting orbit	LEO	LEO	LEO

requires a power conversion system to turn the thermal energy into electrical power. Power conversion systems require many components including a heat rejection system. For fission systems, the power conversion system is typically much heavier than the reactor itself. A common criticism of electric propulsion is that while the propellant requirements are clearly reduced the mass of the power source required to run the electric propulsion has taken the place of the propellant. This is a valid criticism. However, the counter argument in favor of electric propulsion is this: nuclear thermal and chemical propulsion have hit their physics limits. Both of these technologies are bound by the laws of physics to have exceedingly high propellant requirements; later generation of chemical and nuclear thermal rocket will not be significantly improved. Chemical rockets are limited by the amount of energy attainable from combustion, and nuclear thermal rockets are limited by the melting point of the rocket components.

Electric propulsion is challenging due to the engineering of a strong robust power source. However, the power source is an engineering problem that has not come close to approaching a physics limit. Higher performing electric propulsion systems can reduce the propellant required by a much greater degree and later generation of power systems can greatly outperform previous generations.

The power and propulsion system

It is useful to define the electric engine efficiency:

$$\eta_{engine} = \frac{P_{jet}}{P_{power\ source}} \quad \text{Electric Engine Efficiency} \quad (13)$$

Where η_{engine} is the efficiency of the engine in transferring the energy from the power source ($P_{power\ source}$) into the propellant jet (P_{jet}). Thruster efficiency has multiple factors that affect the efficiency including the nozzle efficiency, power density, propellant density, propellant type, input voltages, input amperages, and many other factors which are thruster specific. Eq. (14) now expands from Eq. (12).

Fig. 7 Comparison of NASA DRA 5.0 chemical and nuclear thermal and Ilin's electric propulsion round trip.

Fig. 8 Specific mass and specific power scaling for hall thrusters and the VASIMR engine (Chang-Díaz et al., 2013; Hofer and Randolph, 2013).

$$\alpha_{PPS_e} = \eta_{engine} \alpha_{PPS_{jet}} = \alpha_{power\ source_e} + \alpha_{engine_e} \left[\frac{kg}{kW_e} \right] \text{ Power and Propulsion System Electric Power Specific Mass} \quad (14)$$

Electric propulsion engines have established efficiencies (η_{engine}) and specific masses (α_{engine}). Fig. 8 shows the specific mass estimates for Hall thrusters and the VASIMR engines as a function of power.

Table 9 shows the efficiency, specific power, and specific mass for several electric engines cited in different studies.

The required power source specific mass can now be calculated by assuming a specific thruster.

$$\alpha_{power\ source} = \eta_{engine} \alpha_{PPS_{jet}} - \alpha_{engine} \text{ Power Source Specific Mass} \quad (15)$$

Ilin's work found that an electric propulsion system comparable to chemical and NTP (for a human Mars mission) would have a total power of 5.6 MW of jet power and a power and propulsion specific mass of 20 kg/kW. By using this data in combination with the propulsion system characteristics, we can derive a power source requirement.

The chemical propulsion mission had a different initial mass in low Earth orbit, as well as a different payload mass fraction (10.7% as opposed to 17.4%). In orbital mechanics as well as with the rocket equation, a mission with the same mass fractions and acceleration profiles will produce the same trajectory. Therefore, the initial mass isn't a major concern as long as the payload fractions match. We can therefore make the findings of this analysis applicable to a comparison to both nuclear thermal and chemical systems.

Assuming a thruster specific mass of the of 1.2 kg/kW_{in} and efficiency is approximately 70% using the VASIMR engine data, we can derive the specific mass of the power system that can achieve the $\alpha_{PPS_{jet}}$ that can achieve parity with the respective propulsion systems in Fig. 9. The chemical payload was modified to 38 metric tons to maintain 10.7% payload fraction. This yields a nuclear thermal equivalent $\alpha_{PPS_{jet}}$ of 19.9 kg/kW_e and a chemical $\alpha_{PPS_{jet}}$ of 29.6 kg/kW_e. Table 10 calculates the equivalent power source specific masses.

Table 9 Thruster efficiencies (Chang-Díaz et al., 2013; Hofer and Randolph, 2013).

Thruster	Efficiency (%)	I_{sp} (s)
Hall thruster (Smart 1)	60–75	1000–1600
NEXIS (JIMO)	70–78	6000–7500
NEXT (Dawn)	60–70	3100
VASIMR	60–72	2000–5000

**Fig. 9** Chemical and nuclear thermal analog electric propulsion missions.

A competitive first generation nuclear electric propulsion system should have a performance that is similar or better than other near-term and state-of-the-art systems. A competitive performance would justify the research and development placed into such a technology. Electric propulsion systems are under development that can fulfill the efficiency and specific mass requirements. The power source however is the key area where research and development are needed. The author recommends that a first-generation nuclear electric propulsion system target a specific mass of 10 kg/kW_e. Such a system would clearly outperform state of the art chemical system and would be undoubtedly be competitive likely to outperform nuclear thermal propulsion systems in many scenarios even accounting for some margin.

Historical power source specific mass requirements

In the previous section power source requirements were derived for competitive crewed missions to Mars and used as a general guideline for a competitive electric propulsion system. While the crewed human mission scenarios are a good baseline, it is very challenging to compare performance in a single number. For some missions where time is a major constraint or where ΔV requirements are very low, high thrust propulsion will be very competitive. Aerobreaking, gravity assists and in-situ propellant production are all additional wildcards that can greatly change which propulsion method is more optimal. Table 11 below details different studies that summarize the power and propulsion requirements for different missions.

For example, an unmanned mission to Mars or a mission to an asteroid would most likely have a lower threshold for power and specific power than more difficult manned mission to Mars due to different time constraints. Many sources have cited the specific mass 0.5–1 kg/kW_e as a holy grail of electric propulsion and power systems and 5–20 kg/kW_e as empowering manned missions to Mars.

Fast way to get to Mars one-year round-trip

A one-year round trip to Mars is attractive proposition from the prospective of human safety. What would make a trip possible? One way to travel to Mars and return to Earth in 1 year is with the orbital maneuver described in Fig. 10.

The one-year Mars trip begins in a similar way to the 2-year conjunction class mission though the spacecraft leaves earlier traveling from Earth to Mars. Upon arrival Mars is visited for about a month before returning to Earth using a much longer transit leg that travels slightly inside Earth's orbit around the Sun. Analysis was done by Ilin in 2013 to assess the chemical and nuclear thermal rocket ΔV requirements for a 1 year mission to Mars starting in the year 2033 (Chang-Díaz et al., 2013). His result was that a 1-year mission to Mars required 18 km/s of ΔV for high thrust propulsion systems. Ilin also calculated the ΔV required for an electric propulsion system with 8 MW power and an initial mass of 356 metric tons at 28 km/s. Unlike the previous analysis these missions are assumed to start at the L1 Earth Moon Lagrange point. Fig. 11 illustrates the size of the different propulsion systems to achieve a one-year mission. ****

The graph on the left represents the 18 km/s ΔV for both chemical and nuclear thermal systems based on the rocket equation. The graph on the right represents the 28 km/s ΔV for the electric propulsion. On the x-axis is the I_{sp} and on the y-axis is the percent of the rocket that is not propellant.

Table 10 Power source requirement derivations for conjunction class missions.*Nuclear thermal equivalent power source*

$$\alpha_{\text{power source}} = 0.70 \left[\frac{\text{kW}_{\text{jet}}}{\text{kW}_e} \right] \times 19.857 \left[\frac{\text{kg}}{\text{kW}_{\text{jet}}} \right] - 1.2 \left[\frac{\text{kg}}{\text{kW}_e} \right]$$

$$\alpha_{\text{power source}} = 12.7 \text{ kg/kW}_e$$

Chemical power source equivalent

$$\alpha_{\text{power source}} = 0.70 \left[\frac{\text{kW}_{\text{jet}}}{\text{kW}_e} \right] \times 29.64 \left[\frac{\text{kg}}{\text{kW}_{\text{jet}}} \right] - 1.2 \left[\frac{\text{kg}}{\text{kW}_e} \right]$$

$$\alpha_{\text{power source}} = 19.5 \text{ kg/kW}_e$$

Table 11 Summary of several relevant electric propulsion use cases and specific mass.

Mission study	$\alpha_{\text{power source}_e}$ (kg/kW _e)	Descriptions
Brown and Coates (1966)	16.9	Early suggested human mission to Mars
Jahn (1968)	5.0	Suggested point at which electric propulsion is clearly advantageous over nuclear thermal propulsion for manned missions

Chang-Diaz et al. (2013)	10.0	One Year Mars Round Trips
Chang-Diaz et al. (2013)	14	Suggested point at which electric propulsion can match nuclear thermal performance for number of days in transit
DRM 2002, Drake (2009)	6.7, 5	590 day and 550 day opposition round trip to Mars
Clark et al. (1994)	11.1	960 day conjunction class round trip to Mars

Assuming an I_{sp} of 450 s and using the rocket equation, a chemical rocket would require over 98% of its initial mass to be propellant. This is not feasible. The mass of the propellant tanks alone would be more than 2% allowing no room for a payload. Using chemical propulsion to achieve 18 km/s of ΔV cannot be done unless an “in situ” propellant from Mars (propellant mined on Mars) could be utilized to refuel the rocket around Mars.

For a nuclear thermal system with an I_{sp} of 1000 s a mission could be achievable. With 16% of the rocket remaining after propellant is loaded perhaps half or 8% could be used for the payload. Assuming that the payload is 50 metric tons then an approximate nuclear thermal rocket would be around 1000 metric tons. The propellant requirements for the electric system are heavily affected by the I_{sp} . Going to a higher I_{sp} can greatly reduce the propellant requirements and increase the payload percentage.

The point here is that electric propulsion opens door to incredible missions that could not be otherwise accomplished with existing technology. Electric propulsion could enable manned access to Jupiter, Saturn, and beyond. Chemical simply cannot enable these missions. Even with in situ propellant generation chemical would be very hard. Nuclear thermal perhaps could be adapted to advanced missions across the Solar System but with smaller capability to transport. There is a tipping point at specific masses of 10 kg/kW_e and below that open entirely new kinds of missions that revolutionize space transportation.

Electric propulsion technologies open the door to the Solar System. Electric propulsion comes the closest to being a real spaceship. A craft that can travel from point a to point b in the Solar System without dropping parts of the spacecraft behind for staging. Electric propulsion does not require elaborate infrastructure to put in place. A single electric propulsion craft could be self-sufficient for a trip to and from Earth without requiring “gas stations” along the way that require handling of cryogenic propellants mined from a celestial body. Electric propulsion possesses enough excess ΔV that there is significant operational flexibility. If a crew sets off to Mars and a crew member gets very sick, the spacecraft has the flexibility to reroute to earth.

Electric propulsion can utilize many types of propellant. Typically, Argon, Xenon, or Krypton gas is used currently, however water, Iodine, and even iron can be used as a propellant as any atom can be ionized and accelerated with an electromagnetic field.

Fig. 10 One year Mars trip.

Fig. 11 Isp vs. percent of rocket that is not propellant for both 18 km/s and 28 km/s ΔV .

Therefore, any celestial body could be used to gather in-situ electric propulsion propellant without significant need for mining and extraction; making it much easier to resupply an electric propulsion spacecraft.

The case for electric propulsion

Electric propulsion systems cannot be used within Earth's atmosphere because they need a vacuum to operate. However, once delivered into the vacuum of space, electric propulsion is much better suited to the environment when compared to traditional chemical power systems. Dr. Chang Diaz, the developer of the VASIMR electric engine, likens it to shifting in a car. "You start in first gear, and then you shift to second and third, and so on."

First gear is the chemical propulsion system that delivers the spacecraft to Earth orbit. Chemical rockets are a necessity for quickly allowing a rocket to gain speed and height without crashing the rocket into the ground. Chemical rockets can provide the high thrust to accomplish an orbit. However, the first-gear chemical rocket is not suitable for higher speed, more fuel-efficient travel.

Second gear is an electric propulsion system. While in orbit around the Earth, the spacecraft does not need the high thrust that a chemical engine provides. There is no immediate danger of crashing back into the Earth, so electric engines can use fuel more slowly and efficiently. Similar to the difference between drivers who floor their cars so they won't get good gas mileage and drivers who slowly accelerate their vehicles, electric propulsion gets 10 or more times more ΔV out of its fuel than chemical rockets even when considering the Orbeth losses.

Traditional rockets are expendable. A large rocket begins on the launch pad and comes back as a small capsule. The remainder of the rocket is sometimes recovered and reused, but typically the stages are dropped in the ocean, burn up in the atmosphere, or are dropped in the middle of space. The reason for this is because rockets gain more ΔV if they drop their used, empty fuel tanks before using a new fuel tank.

Electric engines change this staging paradigm. Because electric engines use much less fuel than chemical engines, dropping stages is not as advantageous. This means that electric propulsion rockets making a round trip back to Earth will return in the same state

they left except their propellant tanks will be empty. If the components on the electric propulsion vehicle are built with longevity in mind, the same electric propulsion spacecraft could be used for many trips. Instead of thinking about electric propulsion as a one-shot rocket, electric propulsion can be thought as a car that would just have to replenish its fuel tank to go on the next journey.

Moore's Law is the idea that a technology can improve quickly. For example, computer transistors per square inch of Silicon over the last several decades has followed a trend of doubling every several months. The benefit of investing in a technology that follows Moore's Law is profound after a few generations of doubling.

Liquid and solid rockets have dominated the space propulsion field since before the space race of the 1960s, yet modern chemical rockets perform only slightly better than the first prototypes. The process of combustion is the limiting factor in increasing Isp.

The chemical energy from the combustion provides the propellant with the energy to achieve the exit velocity. There is no clear path to increase the energy derived from combustion. Small gain can be made with different fuel flow cycles, nozzles, higher temperature materials, and fuel additives, but there are few avenues to exponential growth of performance.

Nuclear thermal rockets are limited by the material properties of the rocket engine. Their ISP can be increased by increasing the temperature of the nuclear core that heats the propellant. However, the core's temperature cannot exceed its melting point. Small gains can be made with different ceramic and high-temperature refractory metals; however, there is no foreseeable path for exponential growth.

Electric propulsion has made rapid advances since its beginnings and each generation of electric propulsion has greatly improved upon the last. Electric systems were first used for attitude control and station keeping in the 1970s. Since that time, have greatly increased their Isp and their electrical efficiency. Electric systems are constantly improving. Electric engines are fundamentally based on electric and magnetic fields. Recently inventions (such as high-field strength, lightweight ceramic magnets, and the increasing capacity and temperature ranges of superconducting magnets) have greatly increased the Isp capabilities of electric propulsion, and it appears that they will continue to do so over the coming decades.

There are many types of electric propulsion systems such as hall thrusters, ion engines, arc jets and magneto-plasma-dynamic thrusters (MPD), to name only a few. There are electric thruster designs which span the range of I_{sp} from 500–50,000 s or more with efficiencies ranging from 30–75% efficient. Mature and flown electric thrusters exist for watt to multiple kilowatt levels. At the time of this writing, the nested Hall thruster and VASIMR engine are working toward flight ready systems for power levels at 100 kW (Shark et al., 2019; Anon, 2020). These systems are capable of human missions to Mars. This document will not focus on describing the state of electric propulsion beyond this general summary, but many well written sources exist (Szabo, 2019; Brophy et al., 2011). While there are challenges moving forward, electric propulsion is clearly on a path toward success.

Electric propulsion systems come in three main varieties: electrostatic, electromagnetic, and electrothermal. Electrothermal propulsion is not of much interest here as it uses electricity to heat a propellant directly using an electrode or electric arc. This type of heating cannot achieve an I_{sp} of much over 1000 s. Electrostatic and electromagnetic propulsion utilizes electric and magnetic fields to isolate and heat gas to extreme temperatures. Electrostatic use only electric fields accelerating charged ions of propellant over high voltages to accelerate and heat the ion to a high I_{sp} . The main types of electrostatic thrusters include the gridded ion thruster and the Hall thruster. These types of thrusters require high voltage direct current from a power conditioning system.

Electromagnetic thrusters use a combination of magnetic and electric fields which are often referred to together as the Lorentz force. There are many types of electromagnetic thrusters. Some of the more well-known thrusters include the VASIMR engine and several different kinds of electrode and electrodeless Lorentz thrusters as well as pulsed magneto plasma dynamic engines. These thrusters typically require superconducting magnets and are typically powered by alternating current. Magnets keep charged propellant particles trapped and the propellant is excited often using radio waves or inductive heating. Generally electrostatic thrusters are more mature and simpler technologies, but electromagnetic thrusters can reach higher power densities.

The power source

In the proceeding sections, a specific power of 10 kg/kW_e was established. What kinds of technology are available to achieve the specific power numbers? Historically the only sources of power in space are fission and solar. There are other concepts such as beamed power and fusion that have potential; however, these concepts are removed from consideration because they are not mature technologies or would require a significant buildup of infrastructure over the course of decades.

The case for solar power

Solar powered electric propulsion has been effectively used in several missions to the asteroid belt and within Earth's neighborhood even recently extending to Jupiter. The first use of solar power for beyond Earth orbit electric propulsion was on NASA's 1998–2001 Deep Space 1 spacecraft that passed by an asteroid and a comet. Its 2.5 kW solar arrays powered an NSTAR ion engine. This was followed by Japan's 2003–2010 Hayabusa spacecraft that completed a sample return mission from an asteroid. The European Space Agency also sent a 1.2 kW solar electric spacecraft spiraled out from Earth's orbit to the moon over the course of 3 years. The Dawn spacecraft launched in 2007, visiting the dwarf planet Ceres and the large asteroid Vesta. Solar electric's flight heritage demonstrates that it is a candidate for reliable solar system transportation.

A basic analysis of a solar array's specific power can be found by using the following equation:

$$\alpha_{\text{solar power source}} = \frac{S}{I\zeta} \quad \text{Solar Power Source Specific Power} \quad (16)$$

Where S is the mass per unit area of the solar array including all of the energy components associated with processing the power generated; ζ is the efficiency of the solar cell or solar concentrator in processing that power into electricity; and I is the intensity of sunlight upon the solar panel. Overall power of the solar array is also important to minimize mission times. Solar power is dependent upon the sun. The following graph depicts the solar power density as a function of the distance from the sun. Fig. 12 depicts the solar power available as a function of distance from the sun.

Earth (at 1 AU from the Sun) receives 1366 W/m^2 of solar power. Mars (1.52 AU) receives 43% of that of Earth, meaning that a solar panel array would require over twice the area in orbit of Mars as it would in orbit of Earth. Jupiter has approximately 1/20th the solar energy density of Earth. In addition to distance, temperature is a key parameter that determines efficiency. Temperatures exceeding 100 degrees C for Silicon cells disable them as the thermal energy of the electrons exceeds the bandgap energy. Other semiconductors such as GaAs can achieve higher temperatures but lose efficiency as temperatures exceed $70\text{--}100^\circ\text{C}$. Low temperatures drop efficiency as well in solar cells and -20°C is usually considered to cause low intensity low temperature (LILT) losses. For this reason, solar cells may need to be cooled (or heated), especially if using mirrors to concentrate sunlight or when coming closer to the sun. It is for this reason that solar cells will not be able to greatly exceed the 1300 W/m^2 intensity of sunlight seen near earth without active cooling systems. Solar thermal technologies (as opposed to solar photovoltaic) do not have these constraints and use mirrors to focus sunlight on a heat engine producing electricity. Solar cell efficiencies have been steadily increasing over the last few decades. As multi-junction cells have matured, efficiencies for space solar power can easily obtain close to 40% efficiency.

Solar cells suffer from degradation in the space environment. Generally, that degradation is caused by solar particles. Typically, high efficiency solar arrays degrade 3–6% each year depending on the orbit and particle flux. During a solar event such as a flare they can degrade quickly. The Hayabusa electric propulsion spacecraft experienced a moderate solar flare on its voyage to the asteroid Itokawa. The solar flare damaged the solar cells reducing the cell efficiency by approximately 50%. Photovoltaic cells for spacecraft are designed to be higher efficiency than terrestrial and often have radiation hardening features which reduce degradation such as coatings and redundancy. However, the cost and mass of the systems are affected. Typical space rated solar panels are 100 times more expensive per watt than ground-based systems not counting the launch costs.

Space deployed solar power systems have been steadily increasing as shown in Fig. 13.

Note that the power shown is in the power of the spacecraft's solar panel array at 1 AU. BOL stands for beginning of life as solar panels slowly degrade over time. The International Space Station generates 240 kW of electricity, and it is the highest power, space-based solar panel array.

New launch vehicles are being developed and the cost of delivering mass to orbit has dropped dramatically from \$20,000 per kg to under \$2000 and is may drop under \$1000 per kilogram in the 2020s; a promising development to achieve megawatt scale solar arrays.

Mass per solar panel area depends both on solar panel technology and lightweight structures that can be developed to keep the panels connected to the spacecraft. Having motors and actuators that can direct and point the solar panels to keep the correct orientation to the Sun is also a necessity as well as the technology that manages the solar panels output. Cooling and heating systems may be required. Radiation hardening increases mass as cover glass, thick coatings, and redundancy may be required. The power processing unit (PPU) which processes the input voltage and amperages must also be included in the mass budget as well. Rigid panel solar cells using triple junction cells have been used extensively in space and have specific masses in the range of $15\text{--}40 \text{ kg/kW}_e$ at 1 AU. Flexible fold out arrays can achieve specific masses in the 10 kg/kW_e at 1 AU. Thin film solar arrays are very promising as they are extremely thin

Fig. 12 Solar power density vs. distance from the Sun.

Fig. 13 Space deployed solar power vs. time (Brophy et al., 2011).

Table 12 Energy density.

Fuel	Specific energy (MJ/kg)
Antimatter	90,000,000,000
D-T Fusion	350,000,000
U-235 Fission	82,000,000
Hydrogen-oxygen	15
Gasoline-oxygen	8
Lithium ion battery	1
Lead acid battery	0.2

sheets and can yield specific masses of as little as 0.5–1 kg/kW_e at 1 AU. However, thin film technologies have significant challenges ahead to reach these performance levels and are much more susceptible to space radiation (Beauchamp et al., 2015).

Solar power systems have already shown they can achieve specific masses of 15 kg/kW_e in missions such as NASA's Juno. Near-term technology demonstration such as SpiderFAB, Megaflex, and Rosa and will lead to 10 kg/kW_e (Szabo, 2019; Beauchamp et al., 2015). Solar has and will continue to be a key power source for electric propulsion. Advances in thin film cell technology will continue for the foreseeable future. Challenges based on large scale engineering, long-term reliability, and operational environments can be solved in the long-term and there is a strong industrial push from space based solar power entrepreneurs. The main long-term challenge for solar that remains unsolvable is distance from the sun. Missions beyond Mars will be challenging. Solar may be constrained to the inner solar system. But, within the inner solar system solar electric propulsion will have a future role to play.

The case for a nuclear power source

One kilogram of Uranium-235 has 82 million times the energy of a lithium ion battery (Table 12).

Fusion and antimatter technologies hold promise for the future and both have more energy potential. But fission is a straightforward technology that is ready and capable of providing reliable Solar System transportation and achieving the specific power requirement.

Fission power is rugged. It can operate regardless of proximity or orientation to the Sun and is largely unaffected by the environment. Missions to Jupiter Saturn and other deep space planets would only be possible with nuclear fission technology. Fission would be unaffected by the shadows of planets, or the intense radiation fields from the Van Allen belts or Jupiter's strong magnetic field. Solar flares would pose little threat and micrometeoroid impacts would be mitigated both from the compact size of the spacecraft and the ability to carry more shielding material.

Fission technology also allows scientists and future astronauts to have access to an abundance of energy that enables a new wave of energy intensive activities. For example, access to fission power on the surface of Mars would allow for large scale in-situ operations. Mars has all the ingredients to produce oxygen, water, chemicals, methane and other materials needed for settlement. With

a fission power source in situ manufacturing becomes possible. Fission power systems produce heat that must in general be converted into electricity, however for many of the in-situ processes heat can be used directly. Another chapter in this encyclopedia discusses the benefits and challenges of space fission power (Poston, 2021a).

Space nuclear power flight heritage

Nuclear power's flight heritage is strong. Nuclear Radioisotope Thermal Generators (RTGs) have been used in 44 US deep-space missions, including the Apollo, Cassini, Viking, Mars Science Lab, and Voyager missions. RTG's are passive nuclear power sources that operate on radioactive decay and can reasonably provide around 1 kW of electric power even to the fringes of deep space (Buden, 2011b; Bennett, 2021).

Nuclear thermal rockets have also been developed. From 1959–72 over 20 major ground tests were performed demonstrating that the technology was close to flight-ready (Graham, 2021). Nuclear thermal rockets use the heat energy of the reactor to increase the escape velocity of the fuel (Buden, 2011c; Poston, 2021b).

Fission reactors have been used on over 30 Earth-orbiting satellites, including the SNAP10A, the Russian BUK, and Cosmos radar systems (Voss, 2021). Fission systems are active nuclear power sources that have potential for very high specific power.

Existing and well-studied fission power systems

To date, 33 nuclear fission systems have been launched into space. The first reactor unit was the SNAP10A launched in 1965 as a technology demonstration unit. The last flight reactor was launched in 1988 by Russia. These 33 systems generated on the order of a kilowatt and were used for onboard power rather than for propulsion (Table 13).

Before the advent of electric propulsion, there was little need for medium- and high-power systems because there was no use for them. The Medium Power Reactor Experiment (150 kW) and SPUR program (300 kW) were both space focused ground test reactors from the 1960s; however, they were cancelled because of "lack of mission."

In the mid-to-late 1980s, as electric propulsion began to show signs of maturity, the SP-100 program was started to develop a 100-kW power system. The design was heavily studied and was moving toward flight testing; however, the fall of the Soviet Union, lack of mission, and other factors resulted in its cancellation in 1993.

In 1999 NASA's Deep Space One spacecraft (a solar-powered mission) demonstrated the first use of electric propulsion in beyond Earth orbit applications. This mission clearly demonstrated electric propulsion as viable and helped to spur NASA to again pursue nuclear electric propulsion.

In 2003 NASA Director Sean O'Keefe approved the Prometheus mission to three of Jupiter's moons using nuclear electric propulsion. The Prometheus mission was also known as the Jupiter Icy Moons Orbiter (JIMO) (Buden, 2011a). Prometheus was a 200-kW electric nuclear electric system powered by NEXIS ion engines and Hall thrusters. Work was completed on Phase A of the project, meaning that there were no significant issues with Prometheus, and it was ready to move on to the final design. In 2005 the Administration lowered the priority of the Prometheus mission in favor of the Constellation mission and returning to the Moon. This change in priorities, coupled with a change in the NASA director, the Colombia Shuttle accident, and the \$17 billion estimated Prometheus price tag, resulted in the program's cancellation in 2005. Prometheus represents the first, and thus far, only well hashed out attempt at nuclear electric power for propulsion.

In 2018 NASA completed the nuclear testing of a 1-kW electric Kilopower space reactor prototype (Poston, 2021c), however the project has not proceeded to a flight program. The Jet Propulsion Laboratory has identified several potential NEP missions that could be enabled by Kilopower systems (Casani et al., 2020).

Previously purposed fission power systems

Prometheus is the last well-studied nuclear electric design that could have proceeded as a flight project. However, several designs have been put forth that demonstrate the reasonable capability of nuclear technologies as shown in Fig. 14.

Table 13 Space fission history (Buden, 2011a,b,c; Prost, 2020; Voss, 2021).

System	Launches	Ground reactor tests	Fuel	Thermodynamic cycle	Power	Reactor specific power (W/kg)	Reactor specific mass (kg/kW)
Snap10A (Launched 1965)	1	4	UZrH	Thermoelectric	500 W	1.2	830
RORSAT (1967–1980s)	31	3	UO ₂	Thermoelectric	1.7 kW	2.2	450
TOPAZ (1987–1988)	2	4	UO ₂	Thermionic	5 kW	5	200
SP-100 (Cancelled 1993)	0	0	UN	Thermoelectric	100 kW	19	53
Prometheus (Cancelled 2005)	0	0	UO ₂	Brayton	200 kW	30	33
Kilopower (2015–2018)	0	1	UMo	Stirling	1 kW	3.5	400

Fig. 14 Reactor power scaling (Morrison, 2014).

The blue “flown systems” identify the power systems that have been launched, the SNAP10A, TOPAZ, and BUK on board power systems previously mentioned. The green “studied systems” are systems that have been designed but not built. SP-100 and Prometheus were both heavily studied systems which had identified potential solutions to all known technical obstacles. The red “proposed systems” all fall under the 15–20 MW range. It can be clearly seen that as power increases, the specific mass of the fission power system decreases.

Brayton case study

While there are multiple technologies that can achieve a low specific mass, Brayton cycle technology seems to have the strongest case for near-term development and it is chosen as focal point for achieving a near-term 10 kg/kW_e power system. For the remainder of this section, we will analyze a case study evaluating the design of a Brayton nuclear electric propulsion system that was originally published by Morrison in 2020 (Morrison, 2020). Traditionally closed-cycle Brayton nuclear systems have been limited by temperature to minimize specific mass. There are six recent advancements in the last decade that have been enabling for low specific mass Brayton systems.

1. *Reactor fuels*: Particle fuels capable of operation at temperatures in excess of 1500 K with high burn up capability have reached a high state of maturity (Zinkle et al., 2014).
2. *High temperature turbines*: Turbine reliability has been improved and options for film cooling or ceramic blades have enabled extremely high temperature operation (Torralba, 2016).
3. *Carbon-carbon composite radiators*: Bare carbon fiber radiators with low areal specific mass, flexible construction, and high temperature heat rejection, have been tested and show promise for near-term development (Tombouliau, 2014).
4. *Compact Power Modulation Technology*: Gallium Nitride and Silicon Carbide semiconductor technology have increased efficiency and decreased mass required for power modulation (Anon, 2020).
5. *Reduced Launch Costs*: Specific mass scales very favorably to higher total power. Higher total power requires larger total mass vehicles. Recently, launch prices have reduced by approximately a factor of 10 from the early 2000s and stand to decrease even more into the 2020s based on maturing commercial technologies (Jones, 2018).
6. *Low Enrichment Feasibility*: As the government has been the main customer for space nuclear power system, highly enriched uranium (HEU) has been the focus of nuclear power systems. However, commercialization requires low enriched Uranium (LEU). Low enrichment has recently been shown feasible in the nuclear thermal rocket and this analysis will show that reactors utilizing low enriched Uranium systems can still achieve 10 kg/kW (Venneri and Kim, 2017).

A system model was developed in (Morrison, 2020) for a closed-cycle, direct, multi-stage, recuperated, Brayton cycle and was used to complete a design scoping study to evaluate specific mass. Fig. 15 goes in depth into the model and each of its components.

Each component in the model was modeled either as a design, a trend or correlation back up by literature, or for the power modulation and distribution system (PMAD) a point estimate based on a survey of estimates from other research. The specific mass of the power system a_{sys} is the system mass m_{sys} divided by system electric power P_{sys} and can be defined as the sum of each component’s specific system mass $a_{\text{component}}$.

Fig. 15 Brayton power system model with multiple turbine and compressor stages (Morrison, 2020).

$$\alpha_{\text{power source}} = \frac{m_{\text{sys}}}{P_{\text{sys}}} = \sum \frac{m_{\text{component}}}{P_{\text{sys}}} = \sum \alpha_{\text{component}} \quad \text{Specific Mass Summation} \quad (17)$$

Each component in the system has a specific mass that is primarily a function of temperature or power. $\alpha_{\text{component}}(P_{\text{sys}})$ or $\alpha_{\text{component}}(T_{\text{max}})$. For example, a radiator's mass will scale linearly with heat rejection power; twice the heat rejection requirements will require twice the radiator area for the same temperature. However, radiator area scales with temperature to the fourth power; doubling the temperature will reduce the size of the radiator by a factor of 16. Increasing the temperature will reduce the component specific mass but increasing the rejection power of the component will not reduce specific mass. Another example is a radiation shield. A reactor shield scales semi-logarithmically with power; higher reactor power requires more shielding. A reactor shield however has no direct relationship to temperature. The temperature or power scaling of each of the components in the Brayton system are given in Fig. 1. Because of the intrinsic coupling of power and temperature with regards to specific power, any design must be evaluated with regards to both parameters.

$$\alpha_{\text{system}}(P_{\text{sys}}, T_{\text{hot}}) \approx \sum \alpha_{\text{component}}(P_{\text{sys}}) + \sum \alpha_{\text{component}}(T_{\text{max}}) \quad \text{Temperature and Power Specific Mass Scaling of Components} \quad (18)$$

Combining the power scaling components and the temperature scaling components yields the combined system specific mass scaling with power and temperature. Fig. 16 shows the power and temperature scaling combined into a contour plot.

For a fixed power, a lower specific mass can be attained by increasing temperatures, however it is a diminishing gain as higher power asymptotes to a minimum specific mass. For a fixed-power system it is vice versa. Higher performance cannot be achieved with higher temperature technology. For a given temperature there is an optimum power domain to minimize specific mass that exists in the "knee of the curve" in the contour plot. Low temperature technologies will be competitive at low powers and high temperature technologies will be more effective at higher temperatures. The operational temperatures for stainless steel and Inconel 718 are shown in Fig. 16 to gain a better understanding of temperature on materials requirements. Steel based materials would achieve acceptable performance up to a few hundred kilowatts. Inconel would be for

Fig. 16 Scaling specific mass with power and temperature (Morrison, 2020).

Fig. 17 Scaling of specific power at higher temperature and power. Bar graph of feasible nuclear fuel technology capable of enabling the high temperatures (Morrison, 2020).

a few megawatts. Higher power would be optimized by higher temperatures and would likely require ceramic technology, especially for the turbine and reactor.

Based on the results of the Brayton study, a Brayton power system with a power in the range of 5 MW_e and a hot cycle temperature around 1400–1500 K would be able to achieve a specific mass on the order of 10 kg/kW_e. Such a power system would have a total mass around 50 tons and be launchable on a Falcon Heavy or New Glen class rocket.

High temperature materials are key for ultra-low specific mass. The extreme temperatures shown in Fig. 17 can be achieved by using the advanced carbides (Torralba, 2016).

For advanced nuclear systems ceramics will be an important technology for both the reactor and power conversion systems. Currently terrestrial turbomachinery is working on ceramic blades that can tolerate temperature well over 1800 K but typically require significant maintenance, use film cooling, and have much greater pressure ratios. These more advanced systems could achieve a specific mass below 5 kg/kW_e and potentially as low as 1 kg/kW_e. These more advanced systems could enable fast travel to nearly any destination in the solar system.

Conclusion

Nuclear electric propulsion can be developed in the near future to achieve a 10 kg/kW_e specific mass target. These systems can be iteratively improved in later generations. Increasing power and temperature capability can produce more capable systems expand human presence throughout the solar system and enable a rapid, sustainable travel with efficiency that eliminates the need for significant infrastructure required by chemical or nuclear thermal propulsion. Nuclear electric systems will be able to connect all the planets in the Solar System and facilitate large scale human and cargo transportation. The power systems developed for electric propulsion are synergistic and can be adapted for surface power and support outposts, industrial production, settlements, food production, and much more. Even if chemical propulsion is a predominant propulsion technology, nuclear power sources will be key for exploration and power production. I encourage the bright minds reading this to further develop the systems needed to make nuclear electric propulsion a reality.

Introduction

The distances between destinations in space are significant. The galaxy and the solar system are mostly empty space. Although travel on the Earth's surface is measured in miles, travel between planets is measured in billions of miles. Typically, distances to targets within the solar system are more often discussed in astronomical units (AU), i.e. the distance from the Earth to the Sun. Since 2012, 1 AU has been defined as exactly 149,597,870,700 m, or about 150 million kilometers or 93,225,000 miles. For examples, Saturn is 9.6 AU from the Sun and Pluto ranges between 30 and 49 AU. However, the nearest star, Proxima Centauri b, is 270,000 AU from our Sun, 24.8 trillion miles. Travel between stars is measured in light years (LY), the distance light travels in 1 year or 5,868,000,000,000 miles. To travel these distances in reasonable time will require significantly higher velocities than have been achieved by human missions so far.

Historically, in-space propulsion systems have relied on one simple principle—expel mass in one direction to push your ship in the opposite direction. The higher the speed of the ejected mass means that less mass has to be ejected for a given change in momentum of the ship. Typically, the speed of the ejecta is related to temperature of the gas. Chemical systems use combustion to provide the high temperature. Nuclear rockets use fission heating. Electric thrusters use electro-magnetic fields to accelerate charged gases. The higher the exhaust velocity, the higher delta-V, or change in velocity, can be acquired by the ship.

Most advanced propulsion concepts simply involve methods to increase the velocity of the expelled material in order to reduce the amount of the exhaust mass. If the energy for the propulsion is contained on-board the ship, then very high specific energy, joules per kilogram, sources are needed. The first part of this article will examine concepts which have been proposed that have very high specific energy and produce very high specific impulse. The concepts include fusion (fission-fusion, antimatter driven fusion, and fusion only), and antimatter (direct and sails).

Several alternative ideas have been proposed in which the energy for the mission is not on-board the ship. These concepts have the advantage of not having to have high specific energy and can be massive. However, the concepts must transport the energy over the distance to the ship to provide thrust at the ship. The second part will examine concepts where the energy source is roughly stationary (on Earth or in orbit) and beams the power to the ship via particles, laser, or microwave.

Over the years, the entire idea of momentum transfer in normal space has been called into question. Must a ship progress from two points in space through every point in between? Quantum mechanics indicates that particles can be entangled at a distance for

example. Is it possible that space can be altered or “short circuited” to provide rapid transport between locations? Some concepts have been proposed that invoke trans-dimensional rifts (e.g. the Stargate), mass to energy conversion and transport (e.g. teleportation), space warp (e.g. the Alcubierre effect), reactionless drive (e.g. EM drive). All of these concepts rely on physics which has not been proven. The third part of this article will provide brief summaries of the issues involved in these concepts.

Part 1: On board energy sources

The Voyager II spacecraft launched in 1977 has just reached the 115 AU distance in 2019. The New Horizons spacecraft, launched in 2005, had the highest average transit speed of any spacecraft and took 10 years to travel the 35 AU to Pluto. The distances traveled are modest on the scale of interstellar travel. The velocities obtained are wholly insufficient for regular transport throughout the solar system.

Traveling to destinations in space inherently requires high velocities due to the tremendous distances that have to be traversed. High velocities translate to very high kinetic energy per kilogram of ship mass. That energy has to come from somewhere. If it is contained on board the ship, then the ship at the beginning of the mission must have very high potential energy per kilogram of ship mass to be converted into kinetic energy. Thus, energy sources with high specific energy are needed for advanced concepts.

While fission power and solar power may allow missions between the planets inside the solar system, more energetic reactions will be required to go to the outer planets or beyond. To get a spaceship up to the very high speeds requires energy, or rather high specific energy, i.e. energy per unit mass of the ship.

Table 1 shows some example destinations, their distance from the Earth, and the average velocity necessary to reach them in the designated time. The classical kinetic energy per kg of ship mass is also shown.

In order to reach the specific kinetic energies in **Table 1**, the potential energy of the reactions must have roughly the same magnitude. **Table 2** shows a comparison of specific potential energy for various possible energy sources. Typically, chemical reactions have 10s of MJ kg⁻¹ with the maximum of 142 MJ kg⁻¹ for liquid hydrogen and liquid oxygen, LH2/LOX. Fission based systems have around 70,000,000 MJ kg⁻¹, i.e. over 500,000 times the energy content per unit mass of chemical combustion. Fusion of a proton and Boron-11 (pB11) is even higher at 750,000,000 MJ kg⁻¹.

Comparing the specific energies between the tables shows that chemical combustion is wholly insufficient for transport to the outer solar system. Fission systems with realistic burn-up fractions have just sufficient potential energy to reach beyond the solar system but not much farther. For missions well beyond the solar system or to the stars will require fusion or antimatter.

Most propulsion systems execute impulsive burns, i.e. the thrust is generated for short interval and then the ship coasts until reaching the destination. During the burn, for a fixed exhaust velocity of the propellant and a constant power output of the system, a ship will increasingly accelerate as the propellant is expelled and the mass of the ship decreases. The final velocity achieved by impulsive propulsion systems is clearly summarized in the well-known rocket equation:

$$M_{\text{final}}/M_{\text{initial}} = \exp(-\Delta V/V_{\text{exhaust}})$$

where M_{final} is the final mass of the ship after all propellant is used, M_{initial} is the initial mass of the ship at the start of the mission and equals dry mass plus propellant mass, ΔV is the change in velocity, i.e. delta-V, required, and V_{exhaust} is the exhaust velocity of the propulsion system. The exhaust velocity is usually expressed as specific impulse, i.e. I_{sp} , which equals the exhaust velocity divided by gee, i.e. 9.8 m s⁻². ΔV is determined by the desired mission time. V_{exhaust} is determined by the technology being used.

Table 1 Velocities and kinetic energies required for missions to distant destinations.

Mission	average velocity (km s ⁻¹)	specific energy (J kg ⁻¹)
Kuiper Belt (250 AU in 10 years)	117	6.8e09
Oort Cloud (10,000 AU in 40 years)	1200	7.2e11
Proxima Centauri (270,000 AU in 40 years)	30,000	4.5e14

Table 2 Specific energy contained in selected reactions.

Reaction	Specific energy (J kg ⁻¹)
Chemical combustion (LOX + LH2)	1.4e08
Fission (100% reacting) (realistic burnup—5%)	7.1e13
	3.5e12
Fusion (100% reacting)	7.5e14
Antimatter	9e16

For example, in order to send the probe to Alpha Centauri within a 40 year interval, the average velocity must be greater than 11% the speed of light, c , or roughly $3.3 \times 10^7 \text{ m s}^{-1}$. This is the mission total ΔV . For an impulsive burn mission where the ΔV is acquired quickly relative to the total mission time, one can derive a formula for a minimum total-energy requirement. The minimum propulsive energy required to complete the mission is when the exhaust velocity of the ship is 60% of the ΔV , i.e. $V_{\text{exhaust}} = 0.6 \Delta V$. From the rocket equation, this means that the mass fraction, $M_{\text{final}}/M_{\text{initial}}$, is around 0.2. In this case, then, V_{exhaust} needs to equal $1.98 \times 10^7 \text{ m s}^{-1}$. For a hydrogen atom, this is an energy of 2 MeV. Clearly, at these energies, the exhaust is a high temperature plasma.

Producing MeV scale plasmas with sufficient mass flow for appreciable thrust is the crux of the problem. Such energies are usually relegated to particle accelerators with mass flows of micro-grams per second. Potentially, plasmas created by fusion or antimatter can reach these levels. However, these energies are well above any material vaporization temperature so that use of physical nozzles is unrealistic. Directing the energetic mass into thrust becomes a major problem.

Another major problem for advanced propulsion concepts is power. To cover large distances, the ship must have sufficient thrust to get up to speed. The thrust of the ship, in N, is equal to the mass flow, in kilogram per second times the exhaust velocity, in meter per second, but the power required to provide that thrust is proportional to the square of the exhaust velocity.

High Isp systems, therefore, require very high power. For example, a system with the exhaust velocity of $1.98 \times 10^7 \text{ m s}^{-1}$ and a mass flow of 1 g s^{-1} , has a thrust of 19,800 N and a steady state power level of 196 GW. One of the fundamental problems with on-board energy sources is the huge power levels involved—power levels well outside current operational experience. Consequently, pulsed power systems are often considered which allow very high power levels while producing the same overall energy to the ship.

Conversion to propulsion

As stated earlier, high Isp entails the handling of high temperature plasmas. The temperatures of these plasmas are well above the melting point of any material known. Consequently, the plasmas are often generated in confining magnetic fields to keep the hot materials from the walls. To produce thrust, however, the plasma must push against the ship and be ejected from the confining volume. Several studies have examined the formation of pulsed plasma jets using specially configured magnetic fields. The basis for these concepts is that a fully ionized, neutral plasma will compress magnetic field lines and be reflected away from high field density.

Typically, these studies have relied on large electromagnets (EM) to create the field. The mass of the EM magnets can be reduced by using superconducting (SC) materials to flow the electrical current instead of copper coils. However, superconducting systems require very low temperature and would consume coolant at a fixed rate. Also, SC materials are subject to quenching, i.e. reversion to non-superconducting state, under sufficient irradiation. At velocities needed for interstellar transport, the diffuse material between solar systems could impact the ship at sufficient energies to cause quenching. In addition, for the interstellar mission, the power supplies to drive electromagnets may be too heavy.

Pulsed nozzles

The high power requirements needed for deep space missions does not necessarily require steady state operations. Pulsed operations offer the ability to create very high power with fractional duty cycles. Between pulses, the system has the chance to remove heat so that the average temperature of components is kept lower.

Often, magnetic fields are assumed to be configured to “catch” the expanding plasma and reflect it rearward of the ship to provide the thrust. However, for plasma with sufficient temperature, the photonic emission becomes an issue. The demands on the surfaces that are in line-of-sight to the energy release become difficult. Opaque materials being exposed to pulses of high energy illumination will ablate. This causes loss of material and erodes the surface irregularly. Alternatively, such surfaces can be coated with a thick layer of transparent materials such as sapphire or fused silica which have photon mean free paths of several centimeters and cooled with gas flowing in channels through the material. This allows the surfaces to survive the intense illumination of pulsed systems.

To summarize, on board energy sources suffer from (1) limitations of specific energy of the reactants, (2) need for very high power and very high temperatures of the exhaust, (3) need to keep energetic exhaust from material boundaries, and (4) waste heat removal. Concepts have been proposed that may meet these constraints for a variety of missions (Frisbee, 2003). For interstellar missions, though, only two energy sources meet these criteria for on board propulsion- fusion and antimatter.

Fusion

Fusion occurs between light elements such as hydrogen and helium nuclei at moderate energies due to the relatively low coulomb repulsion between the nuclei. Typically, the atoms must have temperatures in the several 10s of keV to have sufficient impact velocities to overcome the coulomb barrier and merge the two nuclei. However, reaching these temperatures is difficult and containing the high temperature atoms long enough to allow fusion is problematic. To date, no system has operated where more energy has been produced than was required to make the fusion occur, i.e. breakeven.

Because of the high temperatures needed for fusion, the research over the past 60 years has tended to focus on using deuterium-tritium (DT) fuels. The DT reaction cross section peaks around 50 keV, i.e. 550 million degrees Kelvin, at $5 \times 10^{-28} \text{ m}^2$ which is the lowest temperature of the many possible fusion reactions (Santarius et al., 2005).

However, DT fusion produces a 14 MeV neutron in each event. Neutrons require significant shielding and are, essentially, an energy loss mechanism. In short, only around 3.5 MeV per reaction is available for conversion to power or propulsion. All fusion reactions except pB11 and $\text{He}^3 + \text{He}^3$ create neutrons. Consequently, because of the low He^3 cross section, the goal for many researchers has been to find a method to make pB11 fusion a possibility. As the reaction products for pB11 fusion are three, charged, alpha particles, very little shielding is required, a compact system can be built, and the system should be very affordable. The problem is that p-B11 fusion has a peak cross section around 600 keV, 6.6×10^{-9} kelvin, of $1.2 \times 10^{-28} \text{ m}^2$ which is very difficult to achieve in a dense plasma. Thus, the pursuit of this fusion system has languished.

Current fusion systems

Two types of fusion containment have been pursued—magnetic fusion (MF) and inertial confinement fusion (ICF). Magnetic confinement tries to trap the hot plasma in a magnetic bottle and hold it for long periods. Inertial confinement impacts beams of photons or ions onto a target and compresses the material, raising the temperature to fusion conditions. Unfortunately both methods rely on the plasmas reaching thermal equilibrium.

Because of the low density associated with fusion systems, the physical systems are often very large. The International Thermonuclear Experimental Reactor (ITER) is a large, expensive, international effort that hopes to reach break-even within the next decade (Rebut, 1995). The National Ignition Facility (NIF) at the Lawrence Livermore National Laboratory in the US (Miller et al., 2004) is also a large, expensive facility that produces 196 high power laser beams to focus onto a small target to reach the required temperatures.

Fusion propulsion concepts

Several concepts (Santarius and Logan, 1998) have been investigated that use different configurations of magnetic fields to contain the hot plasma long enough for fusion to occur. The primary issue is that net energy must be produced to make the concept effective. Otherwise, if the energy produced is less than the energy required to produce the reactions, the fusion system is simply a complex electric thruster which is more massive than other thruster concepts. Examples of magnetic fusion propulsion concepts that have been investigated are (1) the Field Reversed Configuration (FRC) (Slough, 2001) which uses rotating magnetic fields to create an spherical region in which a torus of plasma is held, and (2) the Dense Plasma Focus (DPF) (Thomas et al., 2005) which uses a large electrical current passing through a jet of gas to ionize and then compress the gas.

An example of Inertial Confinement Fusion (ICF) (Orth, 1998) propulsion is the Vehicle for Interplanetary Space Transport Applications (VISTA) study which uses high power lasers to compress a deuterium-tritium target. VISTA entailed a large ship with a mass of 6000 t to contain the power supplies for the inefficient lasers to produce 17.5 GW of fusion power.

Pulsed fission-fusion—ORION

In the 1960s, Freeman Dyson and others proposed a concept dubbed ORION (Dyson, 1965). The concept would utilize the very high specific power of a nuclear warhead to propel a space ship at high speed. The basic idea required a very heavy “pusher plate” to intercept the explosion coupled to huge shock absorbers to spread out the momentum pulse to the ship. The primary design trades involved (1) the yield of the device and (2) the stand-off distance from the pusher plate. If the device is detonated far enough from the plate to reduce ablation, then the fraction of the explosion that is subtended is small. If the explosion is close so a larger fraction of the blast is accepted, the plate ablates and the Isp is reduced. A major hurdle for the concept was the need for around 10,000 shots to move the massive ship. Placing this many small nuclear devices in orbit appeared problematic from an international agreement perspective. Although the concept was impractical from a variety of political reasons, the basic idea of using pulses to propel a ship is sound.

Pulsed fission-fusion—Puff

The ORION concept offered the possibility of very high power, high Isp, and high thrust. This combination is very hard to produce and very few concepts offer the performance. Unfortunately, the requirement to use compact nuclear devices precluded the development of the concept. An alternative method to produce the explosion, however, may allow ORION type performance with smaller explosions.

The Pulsed Fission Fusion (PUFF) project is a NASA Innovative and Advanced Concepts (NIAC) Phase II that is designing an advanced in-space propulsion concept (Adams et al., 2014). The concept utilizes a very high electrical current (10s of megamps) surrounding a metallic target comprised of fissile material. The current creates an intense magnetic field which compresses the fissile material to reach critical mass. A pulse of neutrons injected into the target will initiate a fission chain reaction which will exponentially grow over a period of 100 s of nanoseconds. The fissile material will reach temperatures in the keV range which will initiate fusion in a central core. The fusion reactions will produce 14 MeV neutrons which will boost the fission process to higher rates. The result is a pulse of plasma with very high temperature producing an impulse of very high power for propulsion with high specific impulse (Isp).

Generation of the high current needed to initiate the pulse requires massive electrical storage systems. The system mass could dominate the ship mass and, ultimately, the effectiveness of the concept. Thus, designing a target that requires the smallest current possible while achieving criticality is a major objective. However, lowering the driving current will push the mass and size of the target higher which will dramatically increase the cost of operating the PUFF system. Thus, an optimum target design may exist that keeps the ship mass low, the driving current low, and the cost of the targets mass low.

Antimatter

Antimatter has the highest specific energy, joules per kilogram, of any material or process known to mankind. Antimatter is the quantum mechanical mirror image of normal matter, i.e. the mass of the antiproton is identical to the mass of the proton but the charge and spin are reversed. Antimatter exists in nature and can be produced in larger quantities via particle accelerators.

Anti-electrons, or positrons, are produced in nature via radioactive decay of isotopes such as sodium-22. They can also be produced by accelerating electrons up to high speed and impinging the beam onto a metal target. While large quantities of positrons can be produced for relatively modest energy expenditure, they cannot be stored with high density because of the space-charge repulsion, i.e. they repel each other so limited amounts can be stored in a given volume.

Antiprotons were first postulated by Dirac in the 1920s (Pais et al., 2005) and discovered in 1955 by Chamberlain et al. (1955) who won the Nobel Prize for the discovery. Antiprotons are not made in our natural Earth environment (but they are seen in Galactic Cosmic Rays) but must be produced in particle accelerators. Both CERN in Europe and the Fermi National Accelerator Laboratory, FNAL or Fermilab, have the ability to produce antiprotons. Fermilab discontinued production a few years ago but the antiproton production line is still intact and can be reinstated. CERN still produces antiprotons at an intensity 1000 times less than the Fermilab rate and decelerates the particles down to low energies (Maury et al., 2014) that can be stored in Penning Traps or used to make antihydrogen. The CERN low energy beam could be used to demonstrate the momentum transfer from fissioning uranium induced by antiprotons for the antimatter sail concept (see below).

Antihydrogen is the combination of an antiproton and a positron to make a hydrogen atom. This is a neutral particle so does not suffer from the space charge repulsion. This allows for the possibility of storing large amounts of antimatter in very small volumes. Currently, antiprotons have been stored in a Penning Trap and combined with positrons to make antihydrogen in the ATHENA experiment at CERN (Rotondi et al., 2005). Conceptually, these neutral antihydrogen atoms can be confined in an Ioffe Trap (Gabrielse et al., 2007) that possesses a high magnetic field gradient. If confined long enough, the neutral atoms should combine to form diatomic antihydrogen molecules. The molecules, if confined in an ultracold cavity will condense to form nano-particles of antihydrogen ice. Conceptually, if the ice particles are exposed to a few positrons, the positrons will annihilate a few electrons leaving the ice particle slightly charged. The charged microparticles can then be manipulated using electric and magnetic fields. Thus, at least conceptually, antiprotons may be able to be stored for decades.

Fermilab produced roughly 1 ng of antiprotons per year at its peak (Thompson, 1994). However, this number is misleading. Fermilab's mission was to capture antiprotons and accelerate them up to 99% the speed of light in order to collide with normal protons to generate exotic particles such as hyperons or the Higgs Boson. To do this, they "accepted" those antiprotons produced in a very narrow energy band so they could be guided by electric and magnetic fields and reaccelerated. Roughly 1 particle in 1 million was accepted. Thus, efficient antiproton accumulation was not the goal.

Consequently, with modest modifications to the existing line, the amount of antiprotons that can be captured at Fermilab could be increased by a factor of 1000–10,000 to raise production to the micro-gram per year level. This will allow the "capture methodology" to be developed that can be used in future high production accelerators.

The next level of production would be to build a new accelerator with a higher beam current. This would allow higher production levels. For example, the LANSCE facility at the Los Alamos National Laboratory (Garnett, 2011) can run a beam current of 1 milli-amp, i.e. 6×10^{15} protons per second. However, it only has an energy of 800 million electron volts (800 MeV). Efficient antiproton production needs an energy of around 50 billion electron volts (50 GeV). A new machine that could produce 1–10 mA at 50 GeV could produce around 0.06 g per year. If the accumulator technology or the beam current could be raised by a factor of 15, then a gram per year might be possible. The accumulator technology can be developed in the near term using the Fermilab facility. The beam current technology may be possible using the superconducting magnet systems developed for the Large Hadron Collider (LHC) in Europe.

Thus, conceptually, a facility that could produce 1 g year^{-1} of antiprotons may be achievable within a 10–20 year period. In parallel, though, the storage of antihydrogen needs to be developed to utilize the material produced. In addition, such a facility will need to be located on a very remote site.

Conversion to propulsion

Antiprotons react with protons and neutrons in normal matter in a process called annihilation. Both protons and antiprotons are composed of quarks. When the two particles annihilate, these quarks are merged and recombine into charged and neutral pions (pions), particles composed of two quarks, with average energies of 250 MeV. The neutral pions decay in roughly a femtosecond (10^{-15} s) to two energetic gamma rays with an average energy of 200 MeV. The main issue then for converting antimatter annihilation into thrust is coupling the very energetic annihilation products into normal matter. The ranges of the pions and gamma rays is very large in matter, i.e. they do not deposit their energy in small volumes. Thus, heating materials requires large numbers of annihilations.

Several concepts have been proposed to convert antimatter annihilation into thrust. These involved (1) depositing the reaction products into a surrounding block of tungsten which would be heated to 3000 K and perform as a thermal rocket with an Isp of 1000 s, (2) surrounding the annihilation region with a solenoidal magnetic field containing a gas which would be heated to plasma temperatures and expelled with an Isp of several 1000 s, and (3) expelling the charged pions directly using a magnetic field with an

Isp of several million seconds but very little thrust. All of these concepts either produced lower Isp or very low thrust. They also entailed heavy massive systems.

Interstellar mission

The goal of sending a human-built probe to the nearest star, Proxima Centauri, would be the most ambitious effort ever attempted. The difficulty of this goal exceeds the development of the atomic bomb, construction of the pyramids, or the Apollo mission to the moon. This is a very hard problem. The Proxima Centauri system is 4.2 light years away, i.e. 24.8 trillion miles. In order to get there in a reasonable time frame, e.g. an individual's career of 40 years, the average speed of the ship must be 0.11 times the speed of light. At this speed, every kilogram of mass of the ship will have 544 trillion joules of kinetic energy which is equivalent to the aircraft carrier Nimitz traveling at 7500 MPH or Mach 11.

Previous studies have assumed very large ships to contain the power supplies, magnets, and systems necessary for antimatter storage. Thus, the amount of antimatter required to acquire the 0.11 c velocity was tremendous (Schmidt et al., 2000). According to the study, many kilograms of antimatter would be needed. This amount of material could not be produced by any means known as yet, would cost more than the US GDP for decades to make, and would represent an extreme hazard for explosion. In short, an intractable approach.

In order to reduce the amount of antimatter required for a deep space mission, two approaches have been investigated—antimatter induced fusion and the antimatter sail. The idea of inducing fusion is attractive in that it uses the antimatter to “enable” a fusion process with net gain. It also produces more energy from fusion than from the antimatter annihilation. Thus, a small amount of antimatter can “light” the fusion reactions. However, large magnets, power supplies, and complex structures are still required. An alternative approach is to drastically reduce the mass of the ship and the complexity of the propulsion system. The antimatter sail concept relies on the use of antiprotons to induce fission in a thin sail. The fission products exiting the surface have an Isp of 1.6×10^6 s, sufficient for an interstellar mission. The main issue for this concept is very high density storage of the antimatter and the ability to handle/manipulate it.

Antimatter induced fusion

Two approaches have looked at using antimatter to initiate fusion. The Antimatter Initiated Microfusion (AIMstar) effort at Penn State University sought to use inertial confinement methods to implode a pellet with fusion fuel using antiproton beams (Lewis et al., 1990, 1999). The pellets were compressed prior to antiproton injection using intense lithium ion beams. Consequently, significant structure was required for the ion beams and power sources. The micro-explosion was induced behind the ship and caught by a magnetic field which expelled the plasma. Alternatively, the Magnetically Insulated Inertial Confinement Fusion (MICF) concept (Kammash, 1998), also relied on laser imploding a spherical target but incorporated the creation of intense magnetic fields in the implosion to reduce energy loss by the plasma, i.e. insulate the plasma so higher temperatures could be reached. After implosion, a small amount, roughly a nanogram, of antimatter was injected into the compressed plasma to heat the plasma and produce significantly more fusion energy.

Antimatter sail

In the NASA Institute of Advanced Concepts (NIAC) study in 2003 (Howe and Jackson, 2005) Hbar Technologies showed that an antimatter driven sail could achieve the velocity required for deep space missions. The basis of the concept was that low energy antiprotons have two unique features: (1) they induce fission in uranium with 100% efficiency and (2) they induce fission on the surface of a uranium sheet allowing the fission products to escape at high speed, i.e. 1.38×10^7 m s⁻¹ or over 1 million seconds of Isp. The NIAC showed that an antimatter driven sail could accomplish the Kuiper Belt mission, i.e. 250 AU in 10 years, for 30 mg of antimatter and the Proxima Centauri b mission in 40 years with 17 g of antimatter. While this amount of antimatter may be possible in the next few decades, creation of the accelerator facility to produce this much antimatter would be expensive and take a decade or more.

Recent work has examined the concept of harvesting antimatter in the solar system (Jackson, 2006). Antimatter is present in Galactic Cosmic Rays entering the solar system. The concept looked at using an orbiting ship to collect the material. Such a concept could reduce the cost of antimatter production and, perhaps, enable propulsion concepts to be implemented.

Part 2: Beamed propulsion

The requirement to carry the source of energy on board the ship puts a huge constraint on the options available. If the energy source can be displaced from the ship, then lighter, less complex ships may be possible. Several concepts have been proposed where the energy source is roughly stationary (on Earth or in Earth orbit) and beams the power to the ship via particles, laser, or microwave. The basic advantage of these concepts is simple—the power generation systems can be massive. The primary issue with all of these concepts is the ability to maintain the energy deposition into the ship as it accelerates away and the distance increases. Thus, the targeting of the beams over large distances and the focusing of the beams onto the ship become the big obstacles. In order to circumvent these issues, very high power must be delivered to the ship so that it can accelerate up to mission speed within a short distance before the beams grow larger than the receiver.

For photonic beam transport, the rate the beam spreads as it propagates, i.e. the divergence, becomes a major issue. The beam divergence (beam spot radius to distance ratio) is proportional to the wavelength of the photons. Typically, beam divergence for visible wavelength lasers is a 0.5 mrad. Thus, for a 10 m^2 sail intercepting the beam in space, i.e. radius is 1.78 m, the beam spot starts to exceed the sail diameter at 3600 m distance. Thrust starts to decrease at this point. Consequently, photonic beamed energy concepts tend to rely on phased arrays of multiple transmitters. By spreading out the transmitter over a larger area and focusing them at a common point in the far field, the beam can be put on target over longer distances and greater speeds achieved. The power per unit area at the ship decreases rapidly with distance. Thus, power levels must be high and coupling the high power into thrust is critical. The divergence for microwave beams is large but the efficiency of generation, i.e. the power density, is good. The divergence for optical frequency photons is lower but the efficiency of generation is low so the power plants to generate sufficient power density at the ship are more massive.

For particle beams such as protons, the divergence of the beam is a function of the “thermal” temperature of the particles. Particle beams are made using electromagnetic accelerators. Facilities on Earth such as Fermilab, CERN and the LHC have demonstrated that bunches of protons can be accelerated up to very high speeds, very close to c . However, the particles in the bunch have a thermal temperature independent of the speed of the bunch. The bunch will also expand due to Coulombic repulsion once the bunch leaves the accelerator.

During the Strategic Defense Initiative (SDI) (Drell et al., 1985) in the 1980s, substantial research was performed at the Los Alamos National Laboratory (LANL) to produce intense neutral particle beams to destroy nuclear warheads coming in from the Soviet Union. These concepts used accelerators in orbit to produce high intensity beams of protons that were neutralized, i.e. turned into neutral hydrogen atoms, at the exit of the accelerator via passage through thin films. This technique would produce a beam of particles that would not expand due to Coulombic repulsion.

While in the accelerator environment, the particle bunch can be “cooled” using electron cooling (Nagaitsev et al., 2006) or stochastic cooling (van der Meer, 1985). This allows the bunch to hold together over greater distances. The material required to intercept and stop the beam of high energy particles cannot be a thin foil as in photonic schemes but must be of sufficient thickness, usually several millimeters. Thus, the mass of the system gets big if large diameters are needed. The typical divergence for a neutral particle beam is essentially the ratio of the particle bunch thermal temperature to the bunch velocity. Thus, for temperatures below 1 eV, the divergence will be well below 1×10^{-6} . Therefore, at a distance of 1 million kilometer, the beam spot would be 1 km in diameter. The primary issues for particle beam propulsion are (1) coupling the incident particle bunch into thrust after impact with the ship and (2) targeting the beam to impact the ship over large distances.

Beamed energy propulsion concepts

Microwaves

Several researchers have examined the use of microwave beams to power the spacecraft. One concept claims high DC to DC efficiency of conversion, 54%, has been experimentally measured (Brown and Eves, 1992) and has shown applicability to missions in the near Earth space.

Another significant effort has looked at millimeter wave technology instead of using microwaves with greater than 10 GHz frequency. The longer wavelength allows for transmission through the atmosphere. In addition, roughly CW operation with mega-joule pulses are claimed to be available currently (Benford and Dickinson, 1995).

High Power Microwave (HPM) sails have also been examined for deep space missions (Benford, 2008). Experiments have demonstrated that stable flight can be achieved using conical sails. Proposed missions include mapping the solar system, exploring the Kuiper Belt, and eventually an interstellar flyby.

Laser beam propulsion

High powered lasers have been proposed for decades to push sails up to high speeds (Forward, 1989). Early concepts relied on extremely large sails with large optical lenses in space to keep the beam focused onto the sail over large distances. This was primarily due to the limited laser power level and the need for longer acceleration times. As power levels have increased, higher power designs have occurred (Kare, 2001).

In 2016, Yuri Milner formed the Breakthrough Foundation and created the Starshot project (Atwater et al., 2018). The goal of the project was to utilize a phased array of very high power lasers, roughly 1 million, on the Earth’s surface to project an intense laser beam to a sail with an area of 10 m^2 and accelerate it up to 20% the speed of light. The mission was to reach Proxima Centauri b in 20 years. The total laser power would be around 70 GW and operate continuously for 1000 s. The sail would experience roughly a 6000 gee acceleration. The payload would be 1 g and the sail would have a mass of around 1 g. Thus, materials issues are a dominant factor in the concept.

The major issues associated with this project are (1) the laser power level, (2) the thermal balance of the sail, (3) the reflected beam destination, and (4) mission flyby time. Current continuous lasers have demonstrated a power level (unclassified) of around 30 kW. The lasers for Starshot need to be up to 1 MW. The thermal balance stems from the amount of the laser power absorbed by the sail and the uniformity of the laser beam spot, i.e. hot spots will evaporate the ultra-thin material. The reflected issue is that 70 GW of laser beam are hitting the sail and “reflected” back. The sail is initially close to Earth. The potential environmental impact of the reflected beam onto the Earth or the passage of the beam through the atmosphere must be closely evaluated. Finally, at 20% c ,

the ship will sail through the Proxima system in a few hours limiting the amount of data that could be collected and transmitted back to Earth.

Particle beams

Particle beam propulsion offers the advantage of large momentum transfer in short time due to the mass of the beam. If the beam is composed of charged particles, then a magnetic field can be employed to reflect the beam so the sail material can be thinner. However, the range of the beam is reduced so accelerations must be higher and targeting the beam through the Earth's and Solar magnetic fields will be difficult. If the beam is composed of neutral particles, the range of acceleration is larger but the sail material must be more massive. Several studies have examined the feasibility of using particle beams for an interstellar mission ([Landis, 2001, 2004](#), [Gilster, 2005](#)).

Particle beams have an advantage of producing higher momentum transfer more efficiently than laser beams so the ground based power may be less. However, the coupling to thrust and the shorter range make the concept difficult.

Part 3: New physics

Over the years, some concepts have been proposed that invoke trans-dimensional rifts (e.g. the Stargate), mass to energy conversion and transport (e.g. teleportation), space warp (e.g. the Alcubierre effect), reactionless drive (e.g. EM drive). All of these concepts rely on physics which has not been proven. The third part of this article will provide brief summaries of the issues involved in these concepts.

Alcubierre drive

In 1994, Miguel Alcubierre published an article ([Alcubierre, 1994](#)) detailing a mathematical description of what has been termed "the warp drive" ([White and Davis, 2006](#)). In the article, he showed that if a region of negative energy can be created in space, then an asymmetry can be created where space is compressed ahead of the spacecraft. The result is that extremely fast transit is possible through space. The concept is similar in description to that posited in the TV show *Star Trek* as the basis for their warp drive. To date, no experimental evidence for the Alcubierre effect has been demonstrated.

EM drive

In 2001, Roger Shawyer proposed a concept that used contained microwave field to impart momentum to the ship via coupling to the quantum vacuum ([Shawyer, 2006](#)). Several researchers have reported results of experiments to prove the concept ([White et al., 2016](#); [Brady et al., 2014](#); [Tajmar, 2018](#)). To date, no definitive results have been obtained clearly verifying the concept. However, thrusts in the micro-newton level and thrust to power ratios of 1.2 mN kW^{-1} are claimed.

Transdimensional gates

A common factor among all advanced propulsion concepts is the assumption that the ship must travel through normal space, i.e. it will occupy every point between its origin and its destination. Consequently, all concepts must increase the speed of the ship to some fraction of the speed of light if missions of reasonable duration are to be achieved. This may cause a problem.

Our solar system is surrounded by the Oort Cloud. The Oort Cloud is a spherical shell of primordial material. Objects in the Cloud can range from asteroid sizes to specks of dust. A ship accelerating up to a fraction of c will be traversing the Oort Cloud at high speed. If every solar system has an Oort Cloud equivalent, then the ship will also be traversing their cloud at high speed.

From the reference frame of the ship, a hailstorm of grit may impact the ship during the transition through the cloud. A grain of sand with a mass of one gram traveling at a speed of $0.1 c$ will have a kinetic energy of $4.5 \times 10^{11} \text{ J}$ or 0.1 kt of TNT equivalent. Thus, impacting small grit during the journey could be catastrophic.

Shielding against such an impact will be very difficult. Using a material shield will be massive. Since the grains may be electrically neutral, a magnetic field will be of no use. If a laser is placed and shoots forward to ionize the grit so a magnetic field could deflect it, the mass of the ship will skyrocket to accommodate the power supply. Thus, interstellar transport through normal space may be precluded.

One solution popular among the science fiction community for decades is the transdimensional transport, i.e. the Stargate/wormhole/teleporter. This concept postulates that two points in normal space can be connected through a "subspace". The common illustration is that normal space is a piece of paper which is folded. By jumping across the gap, fast transit is possible between two points without traveling through every point in between. In 1935, Einstein and Rosen postulated the idea of a "bridge" in space to connect two points. This has later been described as a wormhole through which travel between points could be executed.

In order for transdimensional transport to become reality, significant new physics must be demonstrated. But such a system may be the only method to safely travel between the stars.

Introduction—Regulations for building and launching a space nuclear reactor

Historically, space reactors have been in the domain of government institutions, both in the U.S. and in Russia, and to date, they are the only entities to build and launch space reactors. It is now possible for a commercial company to both build and launch a space reactor. This section covers the regulations for building and launching a space reactor.

The Atomic Energy Act of 1954

The Atomic Energy Act (USC, 1954, AEA) is the fundamental U.S. law for both the civilian and the military uses of nuclear materials. As such, it serves as the basis for other regulations governing the possession, processing, and disposal of nuclear materials and the

operation of nuclear facilities in the United States. The AEA defines the Nuclear Regulatory Commission's (NRC) role in commercial nuclear power and non-government research and defines the Department of Energy's (DOE) role in military uses and government research. (Note, the jurisdiction of the NRC and the DOE is not always clear, given that commercial companies can use DOE facilities.)

The development of a space reactor, including the possession, the processing, and transport of nuclear material, along with the operation of a reactor are governed by the AEA. The agency with jurisdiction will be discussed later and is largely dependent on sites used for reactor development and testing. Recent changes to the Presidential directive site the Department of Transportation (DOT) as the approval authority for the launch of a commercial space reactor.

Launching nuclear material into space is not explicitly covered by the AEA. However, since no entity can possess, process, or transport nuclear material without government approval it is a near certainty that the act applies to the launching of nuclear material by a private company into space.

Designing, building, and testing

Any ground facility for the manufacture of fuel, reactor construction, or reactor testing must be licensed. Jurisdiction for licensing is largely dependent on who owns the site. If the facility were located on a DOE site then DOE would be the regulator and license the facility. If the facility were located on private or non-DOE public property (such as a university) then the NRC would be the regulator and license the facility.

DOE facilities are licensed under 10CFR830 (DOE, 2011). This would cover facilities such as fuel development and manufacture (example: the Y-12 plant in Oak Ridge, TN) or reactor testing (example: the Nevada National Security Site.) If Highly Enriched Uranium (HEU) is used as the fuel, then security requirements will dictate that manufacturing and testing be done at a DOE facility.

Commercial fuel cycle facilities are licensed by the NRC under 10CFR70 (NRC, 2003). A reactor test facility would be licensed by the NRC under 10CFR50 (NRC, 2006). The type of license under 10CFR50 depends largely on the thermal power of the reactor tested. Almost all conceivable space reactor concepts would fit into the research reactor category of 10CFR50. This would lower the regulatory burden and cost considerably. A Low Enriched Uranium (LEU) fueled space reactor could be developed by a private company at an NRC licensed facility.

Any license provided by the federal government will also have to include an environmental analysis under the National Environmental Policy Act (USC, 1970, NEPA). This would take the form of an Environmental Impact Statement (EIS) or Environmental Assessment (EA). Licensing and NEPA activities are lengthy (years) and can be very expensive (10's of millions of dollars). Whether or not a new EIS or EA is required would be a function of the site and its existing NEPA documentation. It is possible the existing NEPA for a site could cover the manufacturing and testing of a space reactor.

Security for the manufacturing and testing phase

All nuclear materials above a de minimis threshold require some degree of security. This can range from a few guards and a simple building and building security plan to a very complex security plan with a building requiring special security devices and specially trained guards.

The NRC and DOE have regulations for the amount of security required based on the type and amount of nuclear material. Currently, the NRC has rules that apply to facilities that handle only LEU and small quantities of other isotopes. DOE has facilities that handle both HEU and/or LEU.

The DOE determines nuclear material security by form, enrichment, isotope type, and amount. For an HEU space reactor that is enriched to 93% ^{235}U using an oxide fuel form, fuel amounts greater than 6 kgs would be Security Category 1, the highest level of security. Almost all space reactor designs using HEU will be Security Category 1. For an LEU space reactor that is enriched to less than 20% ^{235}U the Security Category would be less than Security Category 4, the lowest level of security.

Security Category 1 facilities typically spend 10's of millions of dollars a year on security in the DOE. Less than Security Category 4 facilities would have minimal security costs. Historically, commercial companies such as General Atomic and Atomic International have used HEU, but concerns over the use of HEU are much higher today than in the 1960s and 1970s. Because of the policy concerns for HEU proliferation and the cost issues associated with HEU, it is anticipated that an HEU space reactor would require DOE to maintain a chain of custody for the material from manufacture up to the reactor reaching earth orbit or beyond.

Transportation

Transportation of nuclear material is governed by the Department of Transportation (DOT) under Title 49 of CFR – Hazardous Material Regulation (HMR). Radioactive Material is specifically covered in 49 CFR 173 (DOT, 2010). The DOT coordinates with the NRC for the movement of commercial nuclear material and the DOE for the movement of federal nuclear material covered in 10 CFR 71 (DOT, 2011). The NRC certifies shipping packages for the commercial industry, while the DOE certifies packages for DOE.

The transport of nuclear material depends on the amount and the isotope. Small amounts of material are deemed type A and greater amounts are deemed type B. If the isotope is fissile it includes the letter F. LEU has no threshold between type A and B given its low health effects, but it is fissile material. Thus, the transport of fresh Uranium fuel would be type AF.

The type of material determines the requirements for shipping. The requirements must be demonstrated to be met as part of the development of a Safety Analysis Report for Packaging (SARP) on the specific container. A container is certified by either the DOE or NRC using the SARP process depending on the owner of the material. Certification of a container is very expensive and time-consuming.

There are currently no containers for shipping a complete space reactor. A new space reactor would require a new SARP and a new container. However, there are existing containers for shipping fresh fuel if the reactor is shipped in unassembled sub-assemblies.

Another complicating factor for the transportation of nuclear fuel is security. If the nuclear material is HEU or another type of weapons-grade material (an example is plutonium), then high-security requirements would be required. Note that currently, only the DOE is shipping highly secure nuclear material. There currently is no mechanism for a private company to ship highly secure nuclear material, although an agreement with the DOE is possible. Shipping highly secure nuclear material could be extremely expensive and as such is probably not an option for a commercial space reactor company.

Reactor ground testing

A new space fission system may require nuclear ground testing. The testing can be short term (days to months) or long term (years). Short term testing is typically used to determine the performance of the system to steady-state conditions and to a variety of transient situations. Long term testing is required if pre-flight reliability determination is required.

Nuclear ground testing can be very expensive given the regulatory hurdles and waste disposal issues. The cost can vary widely, depending on the site, security issues, presence of existing infrastructure, and length of the test. The need for testing must be carefully weighed against the benefits prior to going to space. The cost of nuclear ground testing may exceed the cost of performance testing in space. This decision will be very specific to the application and the type of space reactor that is desired.

Two primary regulators can be involved depending on where testing is done. If testing is done at a Department of Energy (DOE) Site, then DOE will be the regulator. If a non-DOE site is used for testing, then the regulator will be the Nuclear Regulatory Commission (NRC). There will be small advantages to either regulator, but in general, the requirements for testing will be very similar. The DOE sites will be governed by 10CFR830. The NRC sites will be governed by 10CFR50. The cost of producing a safety analysis report (SAR) for both regulators can be several million dollars. The cost of managing a test to the requirements of the SAR will also involve costs in the millions of dollars.

The use of highly enriched uranium (HEU) will necessitate that the space reactor is tested at a DOE site. HEU requires a high level of security that only exists in the DOE. The DOE security costs at facilities that perform nuclear testing of HEU are typically in the tens of millions per year. How much of the security costs for testing an HEU system that is borne by the company will have to be negotiated with the DOE. If LEU is used, then security costs will be minimal. Many universities, national laboratories, or private entities may have adequate facilities for testing LEU systems.

Existing infrastructure that does not need to be modified is ideal to keep costs low. Modifying existing infrastructure can be expensive since most necessary modifications are typically required by the SAR and come with nuclear safety grade quality assurance requirements. Building new infrastructure is very expensive because all of the construction will be required to be done under very strict nuclear safety quality assurance requirements.

Finally, if the test is short-term, then the cost of the test is lower. This may also mean that the reactor core (the fuel) has undergone very few fissions and might not be considered waste. If the test is long term, the cost is higher and the company may have to pay disposal cost for the reactor core.

Launch safety and safeguards

The approval for launching a nuclear system into space was updated on August 20th, 2019 by the Trump Administration. The presidential memorandum, *Presidential Memorandum on Launch of Spacecraft Containing Space Nuclear Systems* (NSPM-20, 2019), presents the new process and requirements for launching nuclear systems (both reactor and radioisotope) into space. It also for the first time covers commercial as well as government agency launches.

Historically, this approval process began in the Kennedy administration in 1961. McGeorge Bundy authored a memo to the National Aeronautics and Space Council (NSAM 50, 1961) requiring presidential approval (phrased as any announcements) for launching nuclear power into space, with emphasis on the Space Nuclear Auxiliary Power (SNAP) program. NSAM 50 was revised by the Johnson Administration in April 1965 about the time of SNAP-10A launch (the launch of the only U.S. space reactor). NSAM 50 was replaced by presidential directive NSC-25 during the Carter Administration and was signed by Zbigniew Brzezinski. NSC-25 (1977) formalized the requirement for government agencies to obtain Presidential approval through the Office of Science and Technology Policy (OSTP) for launch. NSC-25 covered the launch of a nuclear system by any agency with multiple agencies included in the approval process depending on the mission. NSC-25 was used to launch multiple radioisotope missions, such as Cassini and New Horizons missions. The new NSPM-20 replaces NSC-25 and will be the process going forward.

Launch approval process

NSPM-20 has three tiers for approval of a launch. The first tier is for small radioisotope heater units with low radioactive inventories (paraphrase of the actual requirements). The second tier is for large radioisotope units that produce electricity and have much larger radioactive inventories than Tier 1. Tier 2 also includes all LEU fueled reactors because of the potential for criticality accidents during launch. Reactors, in general, have very low radioactive inventories at launch (even lower than tier 1 radioisotope systems), but criticality accidents could impact people local to the accident, so are in Tier 2. Tiers 1 and 2 are approved by the head of the sponsoring agency (for example the NASA administrator). For commercial launches, the Secretary of Transportation (or designee) is the approval authority.

The final tier, Tier 3 is for HEU fueled reactors and any nuclear system that exceeds the risk limits explained later. Tier 3 launches require presidential approval (although this approval will be delegated to the head of OSTP.) HEU reactors are in this tier for security reasons, not safety reasons, since HEU has proliferation concerns. This is a change from the previous processes for launching nuclear systems where all launches required presidential approval.

Safety analysis

For the launch of all nuclear systems, a Safety Analysis Report (SAR) must be prepared. The SAR analyzes the hazardous/radioactive material, the potential accidents that could impact this material, the accident likelihoods, and accident consequences. The main goal of the SAR is to establish the systems, design features, or reactor physics that make the system safe. This goal is accomplished by presenting the risk of launch in terms of probabilities and consequence to the public in terms of dose as measured in rem¹ and then by demonstrating what features of the nuclear system keep risk low. This means that the SAR is a risk-based approach to safety. The risk limits from NSPM-20 are:

- 25 millirem de minimis, below which no probability criteria apply;
- A probability of 1 in 100 for accidents that have a dose of 25 millirem to 5 rem;
- A probability of 1 in 10,000 for accidents that have a dose of 5 rem to 25 rem;
- A probability of 1 in 100,000 for accidents greater than 25 rem.

If accidents with doses are above 25 rem and have a probability of greater than 1 in 100,000, then the launch approval would default to Tier 3 and require presidential approval. For accidents above the other limits, then normal approval by the agency head applies. Additional guidelines for non-terrestrial applications (example: planetary surface) may apply but have to date not been specified.

For space fission reactors, the new process and criteria present a practical and straightforward process to navigate. In general, space fission reactors will have in the 10's of curies² in initial radioactive inventory at launch with the radioactive inventory bounded by approximately 100 curies (assuming the reactor has never undergone fission). Doses at 1 km for extremely bounding conditions will be on the order of 1 millirem. Given the new 25 millirem de minimis, reactor launch accidents due to fires and explosions will be in the low millirem range. A bounding accident should be sufficient to establish that the accident dose is below that value.

The focus of the SAR for space reactors will then be the potential for the reactor accidentally going critical during a launch accident. Examples of such an accident would be the reactor falling into water where water adds neutron moderation causing criticality or the reactor being crushed on impact into an unfavorable geometry causing criticality. For these accidents, the goal will be to show that the probability of the event is below the criteria in NSPM-20. Criticality accidents (with insertion on the order of a few dollars of excess reactivity³) will in general have excursions on the order of 1.E17 to 1.E18 fissions. This result will produce doses on the order of a few hundred millirem and will therefore have to be shown to have a probability of less than 1 in 100. This is not hard to achieve with the proper design of the reactor, nor hard to prove with simple experiments and calculations. The reactor designer can add features that aid in the prevention of criticality accidents and include such choices as high length to diameter ratios for the reactor core⁴ or added poisons in the reactor core.⁵ These design choices will be specific to the reactor design.

The re-entry of an RTG or space reactor can have a serious impact on the Earth's population and environment. An RTG or space reactor may burn up on re-entry, however, the few historic accidental re-entry events (such as Cosmos 954, see [Heaps, 1978](#)) also indicate that the system could break up and scatter radioactivity across the Earth.

The operations of an RTG and space reactor where human life is involved will require analysis that evaluates the impact of accidents and power source failure on astronaut health.

¹Rem = Roentgen Equivalent Man; a measure of a dose of nuclear radiation. 1 rem = 0.01 Sievert (SI unit for equivalent dose).

²1 Curie = 3.7×10^{10} integration per second (of radioactive material).

³A reactor core having 1 dollar of excess reactivity is "prompt critical"; it does not need delayed neutrons to maintain criticality. With several dollars excess reactivity the chain-reaction will grow up exponentially very fast until the immense heat generated will disassemble the core.

⁴Heating of a high length-to-diameter ratio core will result in significant negative reactivity insertion.

⁵Presence of burnable poisons in a fast spectrum core can eliminate criticality upon immersion in water.

Review process

The review of the SAR is done by the Interagency Nuclear Safety Review Board (INSRB). The INSRB consists of representatives from the Departments of State, Defense, Energy, and Transportation, the Environmental Protection Agency, NASA, and, as appropriate, the Nuclear Regulatory Commission.

The INSRB is tasked with evaluating the quality of the safety analysis and will identify any significant gaps in analysis. The INSRB can recommend areas for additional analysis where it identifies gaps. It is anticipated that the INSRB will use national laboratories to perform some amount of confirmatory analysis in support of the INSRB. The INSRB will write a Safety Evaluation Report (SER) that recommends approval or disapproval to the appropriate approval authority.

Launching a reactor type that has been launched previously

The new launch safety process includes the ability to compare the launch of a previous system to the launch of the same or similar system. The process is similar to the process used by the NRC and DOE for the current licensing of the reactor and nuclear facilities.

For example, for commercial reactors, a design license can be issued that covers the reactor design, but in the context of a generic location or site. Specific differences related to the reactor site would then be addressed after the reactor is sold to a utility and a site chosen. Only issues with the new site that are not “bounded” by the original analysis must be addressed.

For launch safety, the “bounding” insults would be analyzed based upon the expected launch vehicles that would be available. A generic mission would be chosen along with possible mission-specific issues for analysis. This bounding analysis would attempt to examine the worst-case issues for the space nuclear system. Subsequent launches would only deal with new issues that arise for a specific mission. For example, an earth fly-by may have not been addressed in the original worst-case SAR. A mission is now proposed that would allow the reactor to operate after launch to provide electric propulsion while en-route to the outer solar system. The launch requires a fly-by of Earth after the reactor has started up. Since this scenario was not analyzed in the original SAR, the launch approval would require this scenario to be analyzed prior to approval for this launch.

Treaty issues

There are treaty issues to be considered. The United Nations Committee on the Peaceful Uses of Outer Space (UN, 1992) produced a document that outlined the principles relevant to the use of nuclear power sources in outer space. The document is not a treaty, but the U.S. has treated it like a treaty obligation. The requirements are nothing too onerous, but two issues must be addressed. The document requires the use of highly enriched uranium. It is assumed that this was done because that was the fuel used by the U.S. and Russia at the time. However, there is no reason why LEU would not be an acceptable replacement for HEU with respect to this agreement. In the event of an accident, the country of origin must notify other countries. This was a result of a Russian space reactor re-entering the Earth atmosphere and crashing into northern Canada (Heaps, 1978). This was a serious situation for the Russians and it is recommended that low-Earth orbit missions be evaluated carefully by any commercial space nuclear company.

Summary

A commercial company building and launching space nuclear reactors is now part of the U.S. regulatory structure and as such a private company can design, build, ground test, transport, and launch a space reactor. Regulation of the ground activities would depend on where the manufacturing testing and construction occurred and by the amount of enrichment of the fuel. Launching a reactor by a commercial company is now possible given the new Presidential directive, NSPM-20. This directive provides the approval authority for launch (the head of the sponsoring agency for government missions and the head of DOT for commercial missions.) New criteria have been established for launch safety that favors launching space reactors.

Glossary

Aspect ratio The ratio R/a , where R is the torus major radius and a the (horizontal) minor radius.

Beta β : Ratio of the volume averaged plasma thermal pressure, $\langle p \rangle$, to the pressure exerted by the toroidal magnetic field at the plasma center, $\beta = 2\mu_0 p B_t^2 / 0$. β is typically quoted in percent (Wade, 2021; Lao et al., 2021).

Bremsstrahlung 'Braking radiation': radiation emitted from a plasma via the interaction (deceleration) of free electrons with ions.

Burning plasma Plasma in which heating is dominated by fusion products of thermonuclear reactions, i.e. α -particles in deuterium-tritium plasmas.

Energy confinement time $\tau_E = W_{th}/P_{loss}$: ratio of the total thermal energy of the plasma, W_{th} , to the total power lost by all mechanisms (transport, radiation etc.), P_{loss} ; under steady-state conditions P_{loss} is equal to the total plasma heating power, i.e. the sum of the α -particle heating power resulting from DT fusion reactions, P_α , and the external heating power injected into the plasma, P_{heat} (Wade, 2021).

FPP Fusion power plant.

Hohlraum 'Hollow cavity': a small metallic cavity which holds the DT capsule in inertial confinement laser-indirect-drive experiments; laser energy is injected into the cavity generating X-rays from the walls which compress and heat the capsule to a density and temperature that enable the fusion of its constituents.

ICF Inertial confinement fusion.

ITER Major tokamak-based facility designed to produce 500 MW of fusion power using deuterium-tritium plasmas; ITER, which means 'the way' in Latin, is an international project under construction in southern France.

keV kiloelectronvolt: temperatures, T , in thermonuclear plasmas are normally quoted in keV ($T(\text{keV}) = 10^{-3} k_B T(\text{K})/e$, with k_B the Boltzmann constant and e the electron charge): $1 \text{ keV} = 1.1605 \times 10^7 \text{ K}$.

MCF Magnetic confinement fusion.

MHD Magnetohydrodynamic (relating to stability behavior of a magnetically confined plasma).

Q_{elec} Electrical gain: $P_{e,gross}/P_{e,circ}$ – ratio of the gross electrical output power of a power plant to the recirculating electrical power required to maintain the plant operation.

Q_{th} Fusion gain: P_{DT}/P_{heat} – ratio of the DT (thermal) fusion output power of a plasma to the input heating power from external sources.

RAFM Reduced-activation ferritic-martensitic: a family of steels in which the alloying elements are chosen to lower the susceptibility to radiation damage and to reduce the long-term activation under neutron irradiation.

Reactivity As applied to thermonuclear plasmas, the product of the reaction cross-section, $\sigma(v)$, for a given reaction (e.g., deuterium-tritium) and the relative velocities, v , of the reacting particles, averaged over the velocity distribution functions of the particle populations (for thermal plasmas, the velocity distribution function is taken to be a Maxwellian), written $\langle \sigma v \rangle$.

TBR Tritium breeding ratio: ratio of the number of tritium atoms bred in the breeding blanket per atom of tritium burned in fusion reactions within the plasma.

*Retired.

Introduction

Thermonuclear fusion research has developed, since its origins in the middle years of the 20th century, into a wide-ranging international program aimed at establishing the feasibility of generating energy for the benefit of mankind from the controlled fusion of light atoms. At its heart is the study of plasmas, i.e. fully ionized gases, at temperatures exceeding those at the center of the sun. However, as the challenges of controlling plasmas under the conditions required for net energy production have emerged and have been understood, if not fully resolved, fusion studies have drawn extensively on ideas, experimental techniques and technology from many other areas of science and engineering. The focus of thermonuclear fusion research remains the achievement of net energy production and the exploitation of fusion as a large-scale energy resource, but the research activities encompass a dynamic and stimulating range of interactions with diverse areas of science and technology.

As introduced by Morse (2021), the idea that fusion reactions produce the energy powering the sun was first proposed by Eddington in 1920, though the quantitative details were not worked out until the 1930s by Bethe and others. The source of energy in the sun's core, where the plasma has a temperature of 1.5×10^7 K and a density of 1.6×10^5 kg m⁻³ (corresponding to $\sim 10^{32}$ protons m⁻³), is the so-called proton-proton cycle, which converts protium (i.e. the lightest hydrogen isotope) into ⁴He. However, reproducing this reaction cycle at the parameters achievable in laboratory plasmas is simply not practical and the focus of contemporary fusion research is the deuterium-tritium (DT) reaction, which is the fusion reaction with the largest cross-section at the temperatures likely to be achieved in laboratory experiments (several 10^8 K). As discussed later, deuterium is relatively abundant in the earth's oceans, but tritium is radioactive, with a relatively short half-life of 12.3 years, and so must be produced within a fusion reactor by the reaction of neutrons with lithium contained within the reactor core structure. The most likely fuel cycle for a fusion reactor at the heart of a power plant is therefore referred to as the deuterium-tritium-lithium cycle, and it is this approach to producing fusion energy which will be the focus of subsequent chapters in this Section.

Although the study of hot, magnetically confined plasmas was initiated in the late 1930s (see, e.g., Braams and Stott, 2002), systematic studies toward the feasibility of producing energy by thermonuclear fusion reactions were not initiated until the late 1940s, firstly by figures such as Thomson, Thonemann and Ware in the UK, followed soon after by Spitzer, Tuck, Post and their collaborators in the US, and Tamm, Sakharov, Artsimovich and collaborators in the USSR. These activities were almost immediately enveloped in the curtain of secrecy under which most early nuclear research was conducted. The recognition of the complexities involved in magnetically confining plasmas with parameters approaching those required for the production of a net energy gain from fusion reactions led to a gradual emergence of the research into the public domain, and this process was essentially completed at the 1958 Conference on the Peaceful Uses of Atomic Energy, held in Geneva under the auspices of the United Nations (United Nations, 1958), at which the leading research communities presented the status of research on magnetically confined 'thermonuclear' plasmas. Since that time, the variety of magnetic confinement concepts has shrunk significantly, but remarkable progress has been made in approaching the conditions for achieving a net energy gain in DT plasmas, particularly in the tokamak (see Galvão and Canal, 2021). Key concepts related to an alternative approach to the controlled production of fusion energy, inertial confinement, emerged from the development of thermonuclear weapons. However, the practical study of inertially confined plasmas in the laboratory only became viable following the invention of the laser in 1960. Although much inertial confinement fusion research remained classified until the 1990s, the field has made remarkable progress toward demonstrating a net energy gain from laser-compressed DT capsules. The status of current studies in experiments, theory and technology across these major areas of contemporary fusion research and the approach to the achievement of large-scale (multi-MW) release of fusion energy are reviewed in the following chapters of this Section.

This chapter provides a brief overview of the major subjects which are discussed in subsequent chapters of *Nuclear Fusion R&D* Section of this Encyclopedia. The Section "**Energy production from the fusion process**" of this chapter introduces the deuterium-tritium-lithium fuel cycle and discusses the perceived advantages of large-scale energy production from fusion which have provided the motivation for the research in this area. The basic parameters allowing a simple characterization of the fusion performance of high temperature plasmas are discussed in the Section "**Measures of plasma fusion performance.**" The Section "**Current status of fusion R&D**" outlines the essential principles associated with the magnetic and inertial confinement approaches to plasma confinement and fusion energy production and the present status of R&D in these major fields. An overview of the topics reviewed in *Nuclear Fusion R&D* is presented in the Section "**Overview of nuclear fusion R&D,**" while the Section "**Conclusions**" provides some indications of the future directions of fusion energy research toward the construction of fusion power plants, which is the ultimate goal of the R&D activities in this field.

Energy production from the fusion process

The behavior of the binding energy curve at low atomic number provides numerous opportunities for producing energy from fusion reactions if a sufficiently high plasma temperature is attained, though this does not guarantee that a net energy gain can be obtained from any given configuration. The proton-proton cycle, which is the source of the sun's energy, is based on the weak interaction and its reaction rate is much too slow for earth-bound applications. Analysis of reaction rates between isotopes of hydrogen and helium have revealed several possible processes that could power a terrestrial fusion reactor. Of these, the deuterium-tritium reaction is the most favored:

This reaction consumes only 0.4% of the mass of the reactants in producing its energy output. In a reactor plasma, the 3.5 MeV α -particle (${}^4\text{He}$) interacts with the thermal plasma particles and provides the heat necessary to maintain the high temperatures required to sustain a high reaction rate, while the 14.1 MeV neutron escapes from the plasma and deposits its energy in the surrounding 'blanket' structure, producing heat for electricity production and, as discussed below, replacing tritium burned in the plasma by reactions with lithium contained within the blanket. The most immediate competitors for application to fusion energy production are those referred to in Fig. 1:

As can be seen in the figure, the DT reaction has the highest reactivity by almost two orders of magnitude at temperatures of $\sim 10 \text{ keV}$ (i.e. $\sim 10^8 \text{ K}$) that are likely to be practical in laboratory-based plasmas under conditions conducive to net energy production (as discussed in greater detail by Wade, 2021). A further reaction discussed by Wade, but again demanding much more challenging plasma conditions for net energy production than the DT reaction, is the proton-boron reaction,

which has attracted attention because the fusion products consist of 3 α -particles and the reaction is therefore almost entirely aneutronic – some neutrons with energies $< 1 \text{ MeV}$ are produced by side reactions – implying a very substantial reduction in the activation of the reactor structure and elimination of the need to produce and handle radioactive tritium. Further discussion of the issues related to the exploitation of so-called 'advanced fuels' for the production of fusion energy can be found in Stott (2005) and Dawson (1981).

The availability of tritium is potentially a major issue for the DT approach to fusion energy production, since its half-life of 12.3 years means that there are essentially no resources in nature, although operation of heavy-water moderated/cooled fission

Fig. 1 The reactivity, $\langle \sigma v \rangle$, averaged over a Maxwellian velocity distribution as a function of ion temperature, T_i , for the D-T, D-D and D- ${}^3\text{He}$ fusion reactions. Note that the reactivity for the D-D reaction is the sum of the reactivities for the reactions in Eqs. (2) and (3), which are essentially equal. Curves are derived from the parametric fits in Bosch and Hale (1992). Based on data published by Bosch H-S and Hale GM (1992) Improved formulas for fusion cross-sections and thermal reactivities. *Nuclear Fusion* 32: 611–631, <https://doi.org/10.1088/0029-5515/32/4/107>.

reactors over the past 50 years or so has generated a stockpile of several tens of kg, perhaps as much as 50 kg (see, e.g., Kovari et al., 2018; Pearson et al., 2018). Since a power plant would consume 55.8 kg of tritium per GW_{th} yr of fusion power production, it is clear that an alternative source of tritium is required. This source is provided by the reaction of neutrons escaping from the plasma with lithium which is stored either as a ceramic or in a liquid form in the so-called ‘breeding blanket’ surrounding the plasma (Bocaccini and Day, 2021). There are two possible reactions with lithium isotopes:

It turns out that, over the relevant range in neutron energy, only the first of these reactions makes a significant contribution to tritium breeding. Therefore, it is foreseen that the lithium content of the breeding blanket would be enriched from the 7.4% content in natural lithium to values of up to 90%. Eqs. (1), (6) and, to a lesser extent, (7) therefore constitute the deuterium-tritium-lithium cycle which is currently expected to provide the most rapid access to the demonstration of significant fusion power gain and to form the basis of fusion energy production in the first generations of fusion power plants. The cycle is illustrated schematically in Fig. 2.

Deuterium and lithium are therefore the essential fuel resources for large-scale exploitation of fusion energy. Fortunately, both are abundant on earth: the natural abundance of deuterium in hydrogen is 1 part in 6700, so that the water in the world’s oceans holds $\sim 4 \times 10^{16}$ kg of deuterium. Assuming that a 1 GWe fusion power plant must produce ~ 3 GW_{th} of fusion power, the annual deuterium consumption would be ~ 110 kg. Operating a fleet of 1000 large (1 GWe) fusion power plants for a billion years would thus consume less than 1% of this deuterium reserve.

The 1 GWe power plant would also need ~ 5000 kg of natural lithium (taking credit only for the 7.4% content of ${}^6\text{Li}$ to breed the ~ 170 kg of tritium fuel required). Currently demonstrated and economically recoverable reserves of lithium are estimated to be $\sim 1.3 \times 10^{10}$ kg in ores and deposits, with the total land-based resource perhaps amounting to $\sim 3.9 \times 10^{10}$ kg (Bradley et al., 2017). Taking only the smaller value, the demonstrated lithium reserves would supply the fleet of fusion power plants for ~ 2600 years. Of course, there is competition for lithium use from a variety of other applications, including the increasing use of battery-powered electric cars, and the figure of 5×10^6 kg of natural lithium required each year to fuel a fleet of 1000 fusion power plants amounts to $\sim 10\%$ of the annual lithium consumption in 2019 (U.S. Geological Survey, 2020). This increasing consumption is also driving further exploration and an increase in identified reserves. Moreover, the use of enriched ${}^6\text{Li}$ in fusion breeder blankets implies that much of the natural lithium within the quoted figure of 5000 kg would produce ‘depleted’ ${}^7\text{Li}$ which could be made available for other applications. It should also be noted that the world’s oceans constitute the ultimate lithium resource, since each liter of seawater contains $\sim 2 \times 10^{-7}$ kg of lithium, yielding a total resource of $\sim 2.8 \times 10^{14}$ kg. If cost-effective means of extraction of lithium from seawater are developed in response to the increasing lithium demand, the timescale over which the D-T-Li cycle could be exploited for the production of fusion energy would extend into millions of years.

Implementation of a large-scale program of fusion energy production would depend not only on the technical feasibility of attaining significant fusion gain, as discussed later, but also on achieving public acceptability, primarily by a convincing demonstration of the safety and environmental aspects of fusion energy. As discussed in greater detail by Taylor (2020), Campbell (2021), and Dunne et al. (2021), analysis of the safety performance of fusion power plant operation, in terms of the risk of radiation exposure to personnel, public and the environment, has confirmed important safety characteristics, in particular, that potential off-normal

Fig. 2 A schematic illustration of the deuterium-tritium-lithium cycle foreseen in fusion reactors to both produce fusion energy (the DT reaction) and breed replacement tritium (the n - ${}^6\text{Li}$ reaction).

events within the plant would not require evacuation of public adjacent to the plant. This was also confirmed by the licensing process under French nuclear regulations for the ITER facility currently under construction in Provence (Taylor et al., 2013).

While the favorable characteristics of fusion energy as an essentially zero-carbon source of energy are recognized, e.g. (Tokimatsu et al., 2003; Yamazaki et al., 2011), a key aspect in the assessment of the environmental impact of fusion is the avoidance of a requirement for long-term storage of radioactive waste resulting either from the fusion reaction products or from irradiation of the reactor structure. Since the products of the DT reaction are helium and neutrons, there is no need for waste storage associated with either product. Irradiation of the reactor structure by neutrons will produce transmutation reactions and radioactive tritium will diffuse into the plasma facing components, and possibly also into elements of the tritium breeding and fuel processing systems. Techniques exist for detritiation of materials following plant decommissioning and a major R&D activity is underway to qualify so-called low-activation materials, e.g. reduced-activation ferritic-martensitic (RAFM) steels (see, e.g., Litnovsky et al., 2021; Stork and Zinkle, 2017 and related papers), which should allow the recycling of structural materials into further fusion power plants approximately 100 years after the decommissioning of the originating power plant.

Measures of plasma fusion performance

While the sun relies on the intense pressure produced by its gravitational force to maintain the conditions for fusion reactions to be sustained within its core, alternative approaches must be found to achieve the production of significant fusion energy in terrestrial laboratories. As is evident from Fig. 1, temperatures of 10–20 keV must be reached to produce significant reactivity, even for DT plasmas, implying that a means must be developed of heating and confining a high temperature plasma for sufficiently long to allow an adequate fraction of the plasma ions to react and produce fusion energy. Two basic methods have been developed to a high level of scientific and technical sophistication: *magnetic confinement* (MCF) and *inertial confinement* (ICF). Since, at these temperatures (in fact, above a temperature of ~ 10 eV), a hydrogen plasma is fully ionized, the use of a strong magnetic field to confine the charged ions and electrons of the plasma, and to minimize the interactions with the surrounding walls of the container, via the Lorentz force is clearly one possibility worth exploring, and so an extensive research program exploiting this approach has been implemented internationally during the past 70 years. Alternatively, if one can deliver an intense pulse of energy to a small capsule of fusion fuel sufficiently rapidly that the capsule is compressed, and the fuel heats and reacts before the energy delivered to the particles causes the resultant plasma to blow apart, it is also possible to obtain a significant yield of fusion energy. This approach relies on the *inertia* of the particles within the capsule to confine the plasma for sufficiently long periods – hence the term inertial confinement. This method has only become viable since the development of sufficiently high-power lasers to deliver intense pulses of energy to a DT capsule (although alternative ‘driver’ technologies are also now available, as discussed later). Nevertheless, the exploration of this approach to fusion energy production has also advanced rapidly in recent decades.

Although both approaches to the confinement of thermonuclear plasmas are conceptually appealing, a key question is the identification of the conditions under which sufficient reactions occur, not only to compensate for the energy used to generate the fusion reactions, but also to produce a sufficient gain in fusion energy so that a practical amount of excess energy is released which can be converted to electricity and distributed on the grid. The detailed considerations related to this question are discussed by Wade (2021), in relation to MCF, and by Atzeni (2021) and Tikhonchuk (2021) in relation to ICF. Lawson (1957) developed an initial response to this question, resulting in a condition, the Lawson criterion, based on the plasma density, n , and the energy confinement time, τ_E , under the assumption that the plasma ion temperature is ~ 10 keV. This criterion is typically quoted in the form,

$$n\tau_E > 1 \times 10^{20} \text{ m}^{-3}\text{s}. \quad (8)$$

This inequality, however, was derived under certain specific assumptions, including conditions for the conversion of thermal power to electrical power and, in essence, it defines a necessary, but not sufficient, condition for the achievement of an approximate balance between input heating power to the plasma and the fusion energy output, a condition generally referred to as ‘breakeven.’

A more general condition which is now widely applied in analyzing fusion energy production in magnetically confined plasmas is referred to as the fusion triple product, $n_i T_i \tau_E$, where n_i is the plasma ion density and T_i the plasma ion temperature. The value of this condition in assessing the approach to net fusion energy production is that in the temperature range of particular interest for the DT reaction, 10–20 keV, the reactivity $\langle \sigma v \rangle$, where σ is the (velocity-dependent) reaction cross-section, v the relative velocity of the reacting particles and $\langle \sigma v \rangle$ represents the average over the reacting particle velocity distributions, can be expressed, to within 10%, as, e.g., (Wesson, 2011),

$$\langle \sigma v \rangle = 1.1 \times 10^{-24} T_i^2 \text{ m}^3\text{s}^{-1} \text{ (with } T_i \text{ in keV)} \quad (9)$$

The criterion on the fusion triple product for *ignition*, the conditions under which the α -particle power produced by fusion reactions provides the power required to maintain the hot plasma (i.e. with no external heating), can then be expressed as,

$$n_i T_i \tau_E > 3 \times 10^{21} \text{ m}^{-3}\text{keVs}. \quad (10)$$

Thus, for example, this condition can be satisfied with $n_i = 10^{20} \text{ m}^{-3}$, $T_i = 10$ keV and $\tau_E = 3$ s, very similar parameters around which the ITER experiment, discussed later, has been designed, but with the aim of achieving $Q_{th} \geq 10$, rather than ignition ($Q_{th} \rightarrow \infty$). It should be emphasized that Eq. (10) has been derived under very specific assumptions, e.g., that there are no

impurities (i.e. ions other than D and T) diluting the plasma, so that the equation establishes a minimum criterion, under essentially ideal conditions, for reaching ignition. It should also be noted that the equation implicitly assumes uniform densities and temperatures across the plasma. However, in any realistic magnetically confined plasma the density and temperature profiles are peaked in the plasma center with a radial distribution, falling to low values at the plasma edge. The fusion triple product reported in the literature is then often expressed in terms of the central values of ion density and temperature. Thus, for example, if parabolic plasma profiles are assumed and central plasma parameters are inserted in Eq. (10), the numerical coefficient in the criterion rises from 3 to 5.

Inertial confinement involves very different plasma parameters from those typical of magnetically confined plasmas, since the reliance on plasma inertia implies a very short confinement time, which must be balanced by the production of much higher densities, assuming that the plasma temperatures are roughly similar in the two cases. Assuming that the compressed capsule has a radius of R_c , a characteristic value for the ‘inertial’ confinement time, τ , is given by the ‘matter confinement time,’ i.e. the time taken for the capsule to expand rapidly as a result of the internal pressure of the plasma,

$$\tau \approx R_c / c_s, \quad (11)$$

where c_s is the sound speed in the plasma. An approximate condition for the achievement of ignition in inertially confined plasmas can then be derived in terms of the ‘areal density,’

$$\rho R_c > 1 \text{ g.cm}^{-2}, \quad (12)$$

where ρ is the mass density of the compressed capsule. Note that the condition is expressed here in cgs units, as is conventionally the case in the inertial confinement analysis. A detailed discussion, with a more precise expression of the ignition conditions for inertially confined plasmas, is given by Atzeni (2021). For comparison with the magnetic confinement parameters given previously, this condition would be satisfied for $T_i \sim 5 \text{ keV}$, $n_i \sim 5 \times 10^{25} \text{ cm}^{-3}$ and $R_c \sim 10^{-2} \text{ cm}$. These conditions are being approached in experiments at the National Ignition Facility (NIF) discussed below.

Both MCF and ICF devices should ultimately evolve into fusion power plants producing electricity on a continuous basis. Whereas MCF devices are designed to confine plasmas under long-pulse, and eventually continuous, conditions with a steady production of fusion power, ICF devices would produce a stream of pulses of fusion energy, one associated with each ‘micro-explosion.’ The measure of fusion performance commonly used in each research field to characterize current experiments therefore differs somewhat. In MCF, the fusion gain, Q_{th} , is a measure of the ratio of total fusion output power to external heating power injected to maintain the plasma operating conditions, and this approaches infinity at ignition. A further measure of fusion gain, often referred to as ignition margin, is the parameter, C_i ,

$$C_i = P_\alpha / P_{loss} = n_i T_i \tau_E / 3 \times 10^{21}. \quad (13)$$

P_α is the α -particle power deposited in the plasma by fusion reactions, while P_{loss} is the power lost from the plasma by all means (transport processes, radiation etc.). In steady-state at ignition, these two factors balance and $C_i = 1$, illustrating the utility of the fusion triple product as a measure of fusion plasma performance, even in experiments where only hydrogen or deuterium is used. Since $P_\alpha = P_{DT}/5$, where P_{DT} is the total fusion power produced by DT reactions, it is straightforward to show that,

$$C_i = Q_{th} / (Q_{th} + 5), \quad (14)$$

so that Eqs. (13) and (14) provide a straightforward conversion between measured plasma parameters and potential fusion gain in DT plasmas. Since experimental studies in ICF currently consist of investigations of individual micro-explosions, the relevant gain factor, G , is usually defined by,

$$G = E_{DT} / E_{driver}, \quad (15)$$

where E_{DT} is the total fusion energy produced by the capsule compression and E_{driver} the laser (or other driver) energy used to compress the capsule. A quantitative comparison of the fusion performance measures in MCF and ICF has been given by Betti et al. (2010).

Current status of fusion R&D

Although the simplest approach to magnetic confinement uses the longitudinal field inside a long straight solenoid, the rapid transport of plasma particles along the field lines leads to unsustainable losses from the ends of the configuration, even when the ends are ‘plugged’ by magnetic mirrors, i.e. regions of increasing magnetic field intensity. This approach has therefore almost entirely been abandoned and, since the 1950s, research has predominantly focused on toroidal devices. As explained in greater detail by Galvão and Canal (2021), within a toroidal configuration, the confining magnetic fields must have a helical structure to provide effective confinement of the plasma particles, and this helical structure is produced by several different techniques. In tokamak plasmas (Zohm, 2021), which have, to date, produced the highest fusion gain, the helical fields are produced by a strong *toroidal* field applied by a dedicated coil system combined with a weaker *poloidal* field produced by an inductively-driven current flowing toroidally in the plasma. The stellarator (Yamada, 2021) has the merit that the helical fields can be produced entirely by external (to the vacuum vessel) coils, which may be continuously wound around the torus, or may be modular, analogous to, but of considerably more

complicated shape than, the toroidal magnetic field coils of the tokamak. A third toroidal configuration that has been extensively studied, but is less favored in contemporary research, is the reversed field pinch, RFP (Zuin, 2021), in which the plasma is confined by an externally applied weak toroidal field combined with a stronger poloidal field produced by an inductively driven current and enhanced by an internal dynamo effect. Typical magnetic field strengths in these devices vary over the range 1–8 Tesla (T).

As understanding of the behavior of magnetically confined plasmas developed, increasingly large and ambitious devices were constructed, since it became clear that plasma fusion performance, in particular the energy confinement time, was strongly coupled to the plasma size. The confirmation in 1969 that temperatures of ~ 1 keV had been attained in the tokamak T-3 at the Kurchatov Institute in Moscow (Peacock et al., 1969) focused attention on this configuration and the range of devices expanded significantly during the 1970s, leading to the construction of a trio of large tokamaks, the Tokamak Fusion Test Reactor (TFTR) in Princeton, USA, the Joint European Torus (JET) at Culham, UK and JT-60 (later modified to JT-60 U) at Naka, Japan. In parallel with the increase in scale of the devices, significant experimental and theoretical developments allowed improvements in the control of plasma stability and purity, which, combined with the scaling of energy confinement time with torus major radius, produced substantial improvements in the values of fusion triple product – by approximately 5 orders of magnitude between 1965 and 1995 (see, e.g., Wade, 2021). All of these facilities conducted experiments in either hydrogen or deuterium (and occasionally in helium) to minimize the activation of the device and allow for continued ‘hands on’ maintenance and upgrades.

Progress in the values of $n_i T_i \tau_E$ achieved by 1990 led to the preparation of the first tokamak experiments using DT plasmas. These were conducted in JET and TFTR, which had been designed to handle the complications of operating with DT fuel, between 1991 and 1997. The experiments produced a maximum fusion power of 10.7 MW in TFTR (Hawryluk et al., 1998) and 16.1 MW in JET (Keilhacker et al., 1999), the latter experiment reaching (transiently) a value of Q_{th} of (0.95 ± 0.17) . A comparison of the fusion output power obtained in the TFTR and JET experiments is illustrated in Fig. 3. The level of (equivalent) fusion performance was extended further in deuterium plasmas in JT-60 U, where a peak value of $n_i(0)T_i(0)\tau_E = 1.5 \times 10^{21} \text{ m}^{-3} \text{ keVs}$ was attained, with a central value of ion temperature of ~ 45 keV (Ishida et al., 1997). An extensive program of tokamak experiments continues to refine the understanding of fusion plasma behavior, with further DT experiments in JET planned in 2021, but much of the emphasis in the tokamak program has moved to the preparations for studies of burning plasmas with $Q_{th} \sim 10$ in ITER, which is due to begin operation in the late 2020s (ITER, 2002; Donn   et al., 2021). In parallel with the increases in fusion performance demonstrated by the largest scale tokamaks, experimental facilities exploiting superconducting magnet technology have been exploring plasma behavior in long-pulse operation out to several hundred seconds, for example, Tore Supra/WEST in France (Jacquinot, 2005; Loarer et al., 2020), EAST in China (Wan, 2007) and KSTAR in Korea (Kwon et al., 2011). An overview of progress in the tokamak experimental program is presented by Zohm (2021), while wide-ranging reviews of the progress in tokamak physics which provides the scientific basis for the ITER design can be found in ITER (1999) and ITPA (2007).

The stellarator concept was developed in the 1950s, but the breakthrough represented by the observation of high plasma temperatures in T-3 caused much of the research focus to shift from the stellarator (and also the RFP) to the tokamak. Continued conceptual developments that generated helical configurations with the potential for achieving an equivalent level of confinement to that

Fig. 3 Overview of the principal results from deuterium-tritium experiments in JET and TFTR during the 1990s. The highest JET fusion power production obtained in 1991 used only 11% T in D (JET Team, 1992), while all other experiments used approximately 50:50 mixtures of DT. The TFTR results obtained in 1994 are taken from Hawryluk et al. (1998) and the JET results in 1997 from Gibson et al. (1998). The JET quasi-stationary plasma with approximately 5 s of fusion power output produced the highest fusion energy of any pulse to date, 22 MJ. Reproduced courtesy of EUROfusion,    EURATOM 2021.

obtained in tokamaks revitalized stellarator studies, and construction of two medium-scale devices was launched in the 1990s. The Large Helical Device (LHD), in Toki, Japan, was brought into operation in 1998 (Iiyoshi et al., 1999), while Wendelstein 7-X, in Greifswald, Germany, began operation in 2015 (Bosch et al., 2017). These devices, which also have fully superconducting magnet systems, are confirming the expectations developed from theoretical analysis. They are achieving levels of performance similar to that of equivalent scale tokamaks while also developing the basis for steady-state operation of magnetically confined plasmas. Further details of advances made in stellarator plasma performance are discussed by Yamada (2021). Progress in increasing the plasma performance in the RFP configuration has been limited by the dominance of large-scale MHD instabilities responsible for the plasma dynamo that forms the field reversed configuration. Experiments such as RFX/RFX-mod/RFX-mod2 (Marrelli et al., 2019) are developing techniques to control these instabilities and contributing significantly to the deeper understanding of instability control in magnetically confined plasmas more generally, as discussed at greater length by Zuin (2021).

The possibility of using intense laser beams to compress a small target capsule of DT fuel to high pressures was recognized soon after the invention of the laser in 1960, but due to the classified nature of much of the relevant R&D, progress in the development of this concept was obscure until the partial declassification of some US research in 1972. Nuckolls et al. (1972) first published the idea of using laser compression of a capsule of DT to reach thermonuclear conditions and produce fusion energy. Although much of the research remained classified until 1994, the declassification of US research in that year made evident the significant progress that had been achieved in all key technology areas and in the physics understanding of the compression process, as well as in identifying the remaining challenges to be resolved to produce a net fusion energy gain. The leading concept in ICF remains the laser-driven approach (Regan, 2021) and two alternative approaches have been developed for compression of the DT capsule, referred to as laser-direct-drive (LDD), in which the laser beams illuminate the capsule directly, and laser-indirect-drive (LID), in which the laser beams are injected into a metallic cavity (or ‘hohlraum’) containing the capsule, generating X-rays from the wall of the cavity that compress the capsule.

The key concept in the inertial confinement approach to fusion is to produce a central hot-spot in the compressed DT fuel which initiates the plasma burn, resulting in the generation of α -particles. The burn then propagates through the compressed fuel due to the α -particle heating of the cold outer layers of fuel. Additional advanced ignition schemes, such as ‘fast ignition’ and ‘shock ignition,’ have also been developed, e.g. (Atzeni, 2021). The LDD and LID concepts across have been extensively studied in major facilities across the international research program in ICF (Finnegan, 2021) and two large-scale multi-beam facilities, the National Ignition Facility (NIF) at Livermore in the US, and the Laser Megajoule (LMJ) near Bordeaux in France, are in operation with laser parameters capable of compressing DT targets to ignition conditions (laser pulse energies of 1.8 MJ and 1.4 MJ, respectively, with pulse widths of several nanoseconds). Gradual progress has been reported from NIF LID experiments which have addressed the elimination of residual asymmetries in the compression and subtleties associated with the detailed pulse shape driving the compression. In experiments with 1.5 MJ laser pulses, areal densities, ρR_c , of 0.3 g cm^{-2} have been achieved, producing a total fusion yield of 54 kJ and ~ 10 kJ of α -particle energy deposited in the hot spot (Le Pape et al., 2018). As illustrated in Fig. 4, these experiments are approaching the critical point at which the deposited α -particle energy would balance bremsstrahlung and conduction losses.

In parallel with the progress in laser-driven ICF, alternative driver approaches using heavy ion beams or X-rays produced by high power Z-pinchs have been developed. As discussed by Seidl (2021), recent research on the former concept has focused on the development of the technology required to support the acceleration of ion beams with the parameters required to investigate high energy density plasmas, leading ultimately to the possibility of heavy ion beam driven compression of a DT capsule. The third major strand in ICF research, involving high power pulsed Z-pinchs to generate compression of fine tungsten wire arrays, thereby producing an intense burst of X-rays that subsequently compress a DT capsule, has also received considerable attention (Gomez et al., 2021). A particularly promising development of the Z-pinch concept is referred to as magnetized liner inertial fusion (MagLIF), proposed in the late 2000s (Slutz et al., 2010). This technique involves the application of a strong (10–30 T) axial magnetic field to a small (5 mm diameter) cylinder which confines DT fuel heated to a temperature of several hundred eV by a multi-kJ laser pulse. On application of the Z-pinch current pulse to the cylinder, it implodes, compressing both the DT fuel and the magnetic flux, so that multi-kilotesla magnetic fields can be produced, contributing to the confinement of the hot plasma produced by the compression. The most recent experiments using deuterium fuel have produced plasma ion temperatures of 3.1 keV and DD neutron yields that would correspond to a DT fusion energy yield of 2 kJ (Gomez et al., 2020). While significant challenges remain in applying this approach to the generation of fusion energy, these results are promising and motivate the further development of this concept.

Overview of Nuclear Fusion R&D

Subsequent chapters in the *Nuclear Fusion R&D* Section are organized to provide an overview of the current status of research in both the MCF and ICF programs, to identify many of the key facilities through which the potential for terrestrial energy production from the fusion process is being explored, to present the progress made in understanding the physics determining the behavior of high temperature thermonuclear plasmas, to highlight the major technological developments supporting the progress in fusion plasma performance, to summarize the physics and technology issues at the forefront of research, to look forward to the devices which will advance research in the coming decades toward the demonstration of significant fusion gain and substantial levels of fusion power production, and to outline the concepts that have been developed to date for fusion power plants supplying baseload electricity to the grid once the major outstanding scientific and technological issues are resolved.

Fig. 4 Overview of the progress in laser indirect drive experiments at NIF: total DT neutron yield as a function of ion temperature, red dots are doped HDC implosions, blue dots are High foot implosions, green dots are Low foot implosions. The neutron yield is plotted against the lowest burn averaged DT ion temperature measured by neutron time-of-flight (NTOF) detectors (Brysk temperature). HDC refers to the high density carbon ablator material that encapsulates the DT fuel and the terms High Foot/Low Foot refer to the shape of the laser pulse used to drive the compression. The black open diamond identifies the point where the energy deposited by α -particles would equal bremsstrahlung and conduction losses. Solid curves are yield extrapolations with temperature using a constant value of areal density, ρr , and adiabat. Reprinted with permission from Le Pape S, Berzak Hopkins LF, Divol L et al. (2018) Fusion energy output greater than the kinetic energy of an imploding shell at the National Ignition Facility. *Physical Review Letters* 120: 245003, <https://doi.org/10.1103/PhysRevLett.120.245003>, © 2021 American Physical Society.

The first part of the Section reviews progress and outstanding issues in MCF. Wade (2021) discusses the basic concepts underlying the realization of net fusion power release in magnetic confinement experiments, and Galvão and Canal (2021) discuss the range of magnetic configurations which are being studied in this area. Key theoretical concepts in the physics determining the behavior of toroidal magnetically confined plasmas are discussed in the following series of chapters (Sarazin, 2021; Jenko, 2021; Lao et al., 2021; Gorelenkov and Sharapov, 2021; Dumont, 2021), while the subsequent chapters review major experimental advances made in the research programs of devices exploiting the three principal magnetic field configurations: tokamaks (Zohm, 2021), stellarators (Yamada, 2021) and RFPs (Zuin, 2021). Considerations influencing the choice of technologies for the fusion core of reactor-scale devices, such as ITER, DEMO and fusion power plants, are discussed by Federici et al. (2020), while the technologies related to plasma ‘auxiliary’ systems such as heating and current drive, fueling, measurement systems and plasma control, are reviewed by Inoue et al. (2021). Critical issues in the development of materials capable of surviving in the demanding environment of a fusion reactor are presented by Litnovsky et al. (2021), and the R&D issues which are being addressed to resolve the major challenges in developing a reactor blanket to breed tritium and generate high-grade heat for electricity generation in fusion reactors are detailed by Boccaccini and Day (2021). Experimental facilities designed to take the MCF program forward to large-scale fusion energy production and to prepare the scientific and technological basis for fusion power plants are discussed by Donné et al. (2021), and design concepts for fusion power plants based on the major magnetic configurations are reviewed by Campbell (2021).

The second part of the Section is devoted to a review of progress in the ICF research program and the key challenges being addressed en route to establishing the basis for a power plant based on inertial confinement. Atzeni (2021) develops the basic concepts characterizing fusion performance in ICF compression experiments, outlining the direct- and indirect-drive concepts, while Tikhonchuk (2021) discusses the physics processes determining the evolution of the capsule compression in greater detail. Key experimental progress made using the principal driver concepts are summarized by Regan (2021), who reviews results from laser-driven experiments, by Seidl (2021), who discusses the development of the heavy ion beam driven approach, and by Gomez et al. (2021), who present advances in the Z-pinch driven approach, discussing both the conventional Z-pinch concept for capsule compression and the more recently developed magnetized liner inertial fusion (MagLIF) concept, which blends elements of magnetic and inertial confinement and which shows considerable potential for realizing significant fusion gain. The major facilities which form the core of the experimental program driving forward the ICF approach to fusion energy production are reviewed by Finnegan (2021), the key technologies, and associated challenges, necessary for the eventual implementation of ICF power plants are presented by Campbell et al. (2021), and a range of design concepts for ICF power plants, together with the issues that must be resolved to establish the necessary scientific and technological basis for their realization, are discussed by Dunne et al. (2021).

If the scientific and technological challenges that are currently the subject of the wide-ranging research programs in the magnetic and inertial confinement approaches to fusion energy can be successfully resolved in the coming decades, the benign safety and environmental characteristics of fusion power plants are expected to provide a strong basis for public acceptance of the technology and its large-scale implementation, assuming, of course, that fusion electricity is economically competitive in the energy market prevailing at the time at which the technology is mature. Taylor (2021) reviews the safety and environmental arguments in favor

of fusion energy and summarizes the experience in nuclear licensing gained through the regulatory procedure applied to the ITER facility in France.

Conclusions

The study of controlled thermonuclear fusion has been underway since the late 1940s and, as presented at greater length in the subsequent chapters of this Section, the intervening decades have yielded significant progress in understanding the behavior of plasmas under the conditions required for fusion energy production, in advancing the theoretical description of the processes determining the behavior of such plasmas, in developing the sophisticated technology required to produce and sustain plasmas at the temperatures and densities appropriate to achieving significant fusion gain, and in demonstrating the production of energy from DT reactions. Important challenges remain to be resolved to establish the scientific and technological basis for the next major step following the ITER/NIF generation of experiments, the construction and operation of a DEMO-class device capable of electricity generation using fusion power. However, the extensive understanding developed to date and the experimental capabilities inherent in the ITER and NIF facilities give confidence that, in parallel with the ongoing wide-ranging science and technology studies being conducted across the international research programs, a practical path exists toward the realization of a future generation of fusion power plants.

Complementing the major scientific and technological thrusts in the fusion research programs, the preparation of the socio-economic basis to support the case for public acceptance of fusion energy is underway. Collaboration with industry is also growing to ensure that an adequate industrial base for the construction of fusion power plants will be in place when required. These are essential measures, but they are complicated by the likely timescale for the implementation of fusion power plants – fusion road-maps developed to guide the future planning of the development program suggest that it is likely to be several decades before this key step is possible (see, e.g., [Donné et al., 2021](#)), though contributions by privately-funded R&D activities complementing the major national and international programs could help accelerate this timescale. Of course, as the technology for fusion electricity production matures, it must also be economically competitive, and this issue will certainly influence the timescale for its implementation. Nevertheless, the long-term and widely distributed fuel resources that are available for fusion energy production, together with the favorable safety and environmental characteristics of fusion energy, provide a significant motivation for the continued development of the science and technology toward the exploitation of fusion energy for the benefit of mankind.

Glossary

Aneutronic Lacking the generation of a neutron (typically high energy) as a by-product of the fusion process.

Aurora Borealis, Aurora Australis Spectacular light shows at the North and South Pole resulting from the interaction of high energy particles with the atmosphere in those regions. Sometimes referred to as the Northern or Southern Lights.

Ballooning Instability Rapid displacement of the plasma due to the local plasma pressure exceeding the restoring strength of the magnetic field line, akin to local stretching of a balloon by air pressure until it ruptures.

Bremsstrahlung radiation Radiation due to the acceleration of charged particles due to their Coulomb interaction with other charged particles.

Coulomb barrier Because the Coulomb force increases strongly as the bodies move closer together, an effective barrier is formed between bodies of opposite charge.

Coulomb force A force between charged bodies that acts to repel bodies of similar charge and attract bodies of opposite charge and increases in strength as the bodies come closer together.

Debye sphere The volume over which local electrostatic potential perturbations due to individual or clustered charged particles can be felt. Outside this volume, these perturbations are screened out by the plasma due to the mobility of the electrons and ions. In fusion plasmas, the Debye sphere is typically very small ($\sim 10^{-12} \text{ m}^3$).

Drift waves Small-scale plasma waves generated by local fluctuations in the plasma, akin to small-amplitude waves in a stream generated by eddies in the water flow.

Ignition Condition in which sufficient fusion power is generated that the system is fully self-sustaining, only requiring the injection of additional fuel. This is akin to the point at which fire in a wood-burning fireplace requires no further heat source to continue burning.

Impurity line radiation Radiation resulting from the de-excitation of electrons from higher to lower energy states within the atom.

Inertial confinement Confinement approach that relies on the inertia of imploding material to compress and maintain the fuel sufficiently hot enough for long enough for fusion to occur.

Kink Instability Rapid displacement of the plasma due to local twisting of the plasma column such that the magnetic field tension can no longer resist the twisting, akin to a rope that is twisted beyond its ability to maintain its stretched-out state (i.e., it starts knotting).

Magnetic confinement Confinement approach that relies on strong magnetic fields to confine and maintain the fuel sufficiently hot enough for long enough for fusion to occur.

Magnetohydrodynamic (MHD) A fluid description of the response and dynamics of plasmas in electromagnetic fields.

Maxwellian distribution A statistical description of the probability that a particle will have a particular energy in a system in thermodynamic equilibrium at a given temperature.

Neoclassical transport The theory of how particle orbits impact collisional transport, taking into account both the basic gyromotion of the particle around the magnetic field line and the motion due to large-scale changes in the magnetic field strength.

Nuclear force A very strong, but very localized, force that holds together the subatomic particles (neutrons and protons) of the nucleus.

Plasma The fourth state of matter in which the constituents are primarily ions and electrons.

Superconductivity The property of zero electrical resistance in some substances, typically achieved at very low absolute temperatures.

Synchrotron radiation Radiation emitted when charged particles are accelerated radially due to the Larmor force ($F = v \times B$).

Turbulence Physical phenomenon associated with rapid changes in the background conditions that have the potential of being highly chaotic (i.e., not smoothly or predictably varying in time or space).

Introduction

The fusion process is readily apparent in nature, serving as the source of energy for billions of stars, and continues to liberate copious amounts of energy from matter throughout the universe. Yet, the conditions for fusion reactions to occur in any significant number are extreme and therefore quite difficult to obtain and sustain in the laboratory (Campbell, 2021). The most fundamental constraint on the fusion reaction occurring is the requirement that the relative energy between the reacting ions be extremely high. To occur, fusion requires two ions to approach each other close enough that the (attractive) nuclear force overcomes the (repulsive) Coulomb force. This simplistic constraint would imply that the particles must approach each other with very high energies (~ 400 keV which is in excess of 3 billion degrees Kelvin). Detailed theory of the fusion process has revealed several physical mechanisms that act to reduce this requirement. Most importantly, ions have the ability to tunnel through the Coulomb barrier at lower energies, enabling fusion to occur at much more modest energies (< 5 keV), though the reaction rate at these energies is quite small. Furthermore, particles in a gas that is in thermal equilibrium have a range of velocities (referred to as a Maxwellian distribution), including high-energy particles that react more readily, leading to non-negligible fusion reactivity at quite modest temperatures (~ 1 keV).

For a variety of reasons, light (i.e., low atomic number) nuclei have the largest fusion reaction rates. Due to the Coulomb barrier discussed above, the charge of the nuclei inhibits the ability of the reactants to closely approach each other, leading to a much higher fusion probability of lower-charge ions than their higher Z brethren. In addition, the ability of an ion to tunnel through the Coulomb barrier decreases rapidly with increasing atomic number and mass, thereby favoring the lightest nuclei. Nuclear resonances affecting the formation of the fusion-produced ion also play a role, leading to large differences between similar isotopes. For example, the deuterium-tritium (D-T) reaction has a broad resonance at modest energies that increases the fusion reaction rate dramatically relative to its D-D or T-T counterparts.

For all these reasons, there are only a few reactions of interest for producing self-sustained fusion on earth. The suitability of any particular reaction is dependent on its intrinsic reactivity $\langle \sigma v \rangle_{fus}$, the total energy released in the fusion process E_{fus} , and the total energy released that can be utilized to self-heat the plasma, E_{fus}^{+-} . Table 1 provides information on each of these quantities along with some other parameters whose importance will become apparent in the subsequent discussion.

Self-sustainment, Lawson criterion, and triple product

The basic requirement for any fusion system to be self-sustaining was first developed by Lawson (1957) in which he asserted that self-sustainment can only occur if the heating power provided by fusion reactions exceeds the loss power (i.e., $P_{fus}^{heat} > P_{loss}$). The fusion power available for further plasma heating per unit volume is given by:

$$P_{fus}^{heat} = \frac{n_{i,1} n_{i,2}}{(1 + \delta_{12})} \langle \sigma v \rangle_{fus} E_{fus}^{+-} \quad (1)$$

Table 1 Physical quantities and fusion metrics for several fusion reactions of interest (data from Bosch and Hale, 1992 and Nevins and Swain, 2002).

		E_{fus}	E_{fus}^{+-}	ξ_{m0}	$\langle \sigma v \rangle_{fus, max}$	$T_{(\sigma v)_{max}}$	$n_e T_e \tau_{min}$	$T_e T_i \tau_{min}$
	%	(MeV)			($10^{-22} \text{ m}^{-3}/\text{s}$)	(keV)	($10^{21} \text{ m}^{-3} \bullet \text{keV} \bullet \text{s}$)	(keV)
D + D $\rightarrow$ T + H	0.5	4.0	4.0	4	~ 3.0	> 1000	1000	15
He ³ + n	0.5	3.3	0.8					
D + T $\rightarrow$ He ⁴ + n	1	17.6	3.5	8	10	65	3.0	13.6
D + He ³ $\rightarrow$ He ⁴ + p	1	18.3	18.3	15	2.8	250	48	58
H + B ¹¹ $\rightarrow$ 3He ⁴	1	8.7	8.7	32	4.6	550	1000	123

where $n_{i,1}$ and $n_{i,2}$ are the density of reacting ions, $\delta_{12} = 1$ if the reacting ions are identical (0 otherwise). Note that Eq. (1) assumes that the non-charged particles (primarily neutrons) readily escape the plasma and therefore do not further heat the plasma and hence do not contribute to the power balance.

The loss power per unit volume can be written simply as the energy loss rate from the confining volume:

$$P_{\text{loss}} = \frac{3}{2} \left[n_e T_e + (n_{i,1} + n_{i,2} + \sum n_{Z,k}) T_i \right] / \tau \quad (2)$$

where n_e is the electron density, T_e and T_i are the electron and ion temperature, respectively, $n_{Z,k}$ is the impurity density, and τ is characteristic time constant for energy loss (through all processes). Impurities consists of any non-reactant particles including any of the charged particle products of the fusion reaction itself and impurities eroded from the chamber walls or intentionally introduced for power exhaust control purposes. The dominant loss processes in fusion plasmas of interest are radiative losses (e.g., bremsstrahlung radiation, impurity line radiation) (Jensen et al., 1977), and transport losses. Synchrotron radiation can become an important, additional loss mechanism in cases with very high magnetic fields.

Further constraints are imposed by charge neutrality such that:

$$n_e = n_{i,1} Z_1 + n_{i,2} Z_2 + \sum n_{Z,k} Z_k \quad (3)$$

Here, Z_k is the charge of the respective ions and impurities. Applying this constraint, observing that P_{fus} is maximized when $n_{i,1} = n_e / 2Z_1$, $n_{i,2} = n_e / 2Z_2$ and $n_{Z,k} = 0$, and combining Eqs. (1) and (2) into the self-sustainment requirement $P_{\text{fus}}^{\text{heat}} > P_{\text{loss}}$ yields the so-called Lawson criterion:

$$n_e \tau > \frac{\frac{3}{2} \xi_m T_i}{\langle \sigma v \rangle_{\text{fus}} E_{\text{fus}}^{+, -}} \quad (4)$$

Here, ξ_m is a reaction-specific multiplier. For $n_{Z,k} = 0$, ξ_m is given by:

$$\xi_{m0} = [4f_T Z_1 Z_2 + 2(Z_1 + Z_2)] / (1 + \delta_{12}) \quad (5)$$

where $f_T = T_e / T_i$. Values of ξ_{m0} for various reactions are given in Table 1. For a pure, D-T plasma (i.e., $f_{Z,k} = 1$, $Z_1 = Z_2 = 1$ and $\delta_{n1} = n_2 = 0$) with equilibrated electron and ion temperatures (i.e., $T_e = T_i \rightarrow f_T = 1$), one finds that $\xi_{m0} = 8$ and:

$$n_e \tau|_{D-T} > 12 T_i / \langle \sigma v \rangle_{\text{fus}} E_{\text{fus}}^{+, -} \quad (6)$$

Because $\langle \sigma v \rangle_{\text{fus}}$ is solely dependent on temperature, the right-hand side of Eq. (6) is solely a function of T_i . The temperature dependence of $\langle \sigma v \rangle_{\text{fus}}$ therefore is critically important in establishing the minimum $n_e \tau$. In the intermediate temperature range, $\langle \sigma v \rangle_{\text{fus}}$ scales roughly as T_i^2 ; at lower T_i this dependence is even stronger. These together would imply it is favorable to achieve as high a T_i as possible. However, at higher T_i , $\langle \sigma v \rangle_{\text{fus}}$ scales much more weakly with T_i , and for some reactions that benefit from nuclear resonances at intermediate T_i , $\langle \sigma v \rangle_{\text{fus}}$ actually begins to decrease with increasing T_i . This translates into the minimum $n_e \tau$ occurring at an intermediate T_i for most reactions (e.g. at ~ 14 keV for the D-T reaction).

As will be discussed later, in many cases the maximum attainable pressure in magnetic confinement systems is limited by fundamental properties associated with magnetohydrodynamic (MHD) stability. In such cases, it is more appropriate to rearrange Eq. (4) to form the so-called triple product:

$$n_e T_i \tau > \frac{\frac{3}{2} \xi_m T_i^2}{\langle \sigma v \rangle_{\text{fus}} E_{\text{fus}}^{+, -}} \quad (7)$$

Note that for the D-T reaction with $f_T = 1$, Eq. (7) recovers the typical triple product formula found in the literature of $n_e T_i \tau|_{D-T} > 12 T_i^2 / \langle \sigma v \rangle_{\text{fus}} E_{\text{fus}}^{+, -}$. As an aside, the fusion reactivity for D-T can be approximated in the temperature range of interest as $\langle \sigma v \rangle_{\text{fus}, DT} \approx 1.1 \times 10^{-24} T_i^2$.

Assuming $T_e = T_i$, the fusion triple product given by Eq. (7) for the reactions identified above are shown in Fig. 1a. As anticipated from the discussion on fusion reactivity, the reaction with the most favorable (i.e., lowest) $n_e T_i \tau$ is the D-T reaction with the minimum value $n_e T_i \tau \approx 3 \times 10^{21} \text{ m}^{-3} \cdot \text{keV} \cdot \text{s}$ occurring at $T_i \approx 14$ keV. The minimum $n_e T_i \tau$ for the D-He³ and p-B¹¹ reactions are orders of magnitude higher and occur at significantly higher temperatures. Therefore, while these reactions offer the potential advantage of being aneutronic (eliminating issues related to the damage caused by high energy neutrons), achieving the conditions necessary for a sustained fusion reaction are significantly more challenging.

Impressive progress was made in achieving the necessary $n_e T_i \tau$ in tokamak configurations in the late 1990s, as is depicted in Fig. 2. From the mid-1960s to the mid-1990s, the achieved $n_e T_i \tau$ doubled approximately every 1.8 years, slightly faster than the rate of progress described by Moore's law for semiconductor development (number of transistors on a chip doubled every 2 years). This impressive rate of progress was achieved through the deployment of new facilities with larger plasma size, higher magnetic field, and increased heating power. The next step in this evolution is ITER, a multi-national facility specifically designed to demonstrate sustained operation with $n_e T_i \tau$ values that are needed for future fusion reactors.

It's important to realize that Eq. (5) assumes no fuel dilution due to impurities (i.e., $n_{Z,k} = 0$). If impurities are included in the evaluation of the required $n_e T_i \tau$ (i.e., assuming $n_{Z,k} \neq 0$), the resulting contamination rapidly poses serious challenges to achieving the necessary conditions due to both dilution and increased radiation losses. Even small levels of impurities can cause significant

Fig. 1 (a) $n_e T_i \tau$ and (b) $\beta \tau$ for fusion reactions of interest assuming $n_{i,1} = n_e/2Z_1$, $n_{i,2} = n_e/2Z_2$ and $n_{Z,k} = 0$. Dashed lines represent $n_e T_i \tau$ substituting $\sigma_{fus} \nu$ for $\langle \sigma v \rangle_{fus}$ in Eq. (7). $\beta = p(B^2/2\mu_0)$ is the ratio of the kinetic pressure to the applied magnetic pressure.

Fig. 2 Rate of progress in achieved triple product $n_e T_i \tau$ in tokamak facilities exceeded that of semiconductor development in the late 1990s.

increases in ξ_m through dilutive effects, and by extension, the minimum $n_e \tau$ needed for self-sustainment. An example of the impact on ξ_m is shown in Fig. 3 for helium (a typical fusion product), argon (used for power exhaust control), and tungsten (chamber wall material). For the D-T reaction, a 50% increase in ξ_m from its base level ($\xi_m = 12$ vs $\xi_{m0} = 8$) occurs at $f_{\text{Helium}} = 10\%$, $f_{\text{Argon}} = 1.3\%$, and $f_{\text{Tungsten}} = 0.4\%$. This situation is further exacerbated by the fact that higher Z impurities cause substantial increases in both the bremsstrahlung and line radiation, thereby reducing the effective confinement time τ and making it more difficult to achieve the necessary $n_e T_i \tau$. Hence, the practical limit on impurity levels is much lower than those listed above.

It should be stressed that Eqs. (4) and (7) represent fundamental requirements for self-sustainment of any fusion system. Because of the highly non-linear nature of these parameters and their large variation (many orders of magnitude), approaches that target operating conditions that are off the optimal temperature must deliver significant performance improvements to enable sustained fusion operation. In this respect, while D-T fusion systems with temperatures less than 10 keV are possible, it seems likely that the practical limit for realistic thermonuclear fusion systems will be with $T_i > 10$ keV.

A possible approach to reduce these requirements is to produce an energy distribution of particles that maximizes the fusion reactivity. This is typically referred to as a non-Maxwellian energy distribution in which particles are driven to a particular energy range and not allowed to thermalize within the system. As noted in the previous section, a modest increase in reactivity is obtained. However, one finds that if one simply substitutes $\sigma_{fus} \nu$ (monoenergetic) for $\langle \sigma v \rangle_{fus}$ in Eq. (7) that the minimum value of $n_e T_i \tau$ (where T_i now represents the energy of the population) actually increases and moves to higher energy, with the minimum occurring near the peak in σ_{fus} . This is shown for the D-T and p-B¹¹ reactions as the dashed curves in Fig. 1a. Hence, while counter-intuitive at first thought, the Maxwellian distribution actually improves access to self-sustained fusion conditions due to the non-negligible fusion cross section at lower energies.

Fig. 3 Impact of increasing the impurity fraction for helium ($Z = 2$), argon ($Z = 18$), and tungsten ($Z = 74$) on the reactivity-specific multiplier ξ_m relative to its value with $f_Z = 0$ (DT reaction).

Practical fusion energy

Note that the above discussion assumes that the heating provided by the fusion process alone is sufficient to maintain the required plasma conditions (i.e., $P_{\text{heat}} = P_{\text{fus}}$). This condition is known as “ignition” and will be self-sustaining as long as sufficient fuel is supplied. The requirement on $n_e T_i \tau$ can be relaxed somewhat by applying external heating to supplement the fusion heating (i.e., $P_{\text{heat}} = P_{\text{fus}}^{\text{fus}} + P_{\text{heat}}^{\text{ext}}$). While the use of external heating will reduce the overall efficiency of the fusion system, external heating can be beneficial (and possibly required) in delivering important control capabilities (e.g., burn control, current drive).

Defining the factor $\gamma_{\text{fus}} = E_{\text{fus}}/E_{\text{fus}}^{+,-}$, and representing the external heating as a fraction of the fusion power $P_{\text{heat}}^{\text{ext}} = P_{\text{fus}}/Q_{\text{fus}}$, the triple product requirement can be rewritten as:

$$n_e T_i \tau > \frac{\frac{3}{2} \epsilon_m T_i^2}{\langle \sigma v \rangle_{\text{fus}} E_{\text{fus}}^{+,-}} \left(\frac{Q_{\text{fus}}}{Q_{\text{fus}} + \gamma_{\text{fus}}} \right) \quad (8)$$

The parameter Q_{fus} is generally referred to as the fusion gain since it represents the fusion power produced for a given input power. Note that $Q_{\text{fus}} = \infty$ (or what is commonly referred to as the ignition condition) recovers Eq. (4). As Q_{fus} is reduced and becomes comparable in magnitude to γ_{fus} , the $n_e T_i \tau$ required for sustainment is reduced. For example, for the D-T reaction with $\gamma_{\text{fus}} = 5$, $Q_{\text{fus}} = 10$ results in a 33% reduction in the $n_e T_i \tau$ requirement while $Q_{\text{fus}} = 5$ yields a 50% reduction.

While Eq. (8) suggests that lowering Q_{fus} is advantageous in lowering the $n_e T_i \tau$ requirement, one must be aware that there are practical limits on the minimum value of Q_{fus} if the goal is to produce net electricity. Assuming that the system is able to recover all the thermal power generated by the fusion process, the net electricity $P_{\text{electricity}}$ produced by the system can be represented as:

$$P_{\text{electricity}} = P_{\text{fus}} \eta_{\text{th}} M_{\text{bl}} - \frac{P_{\text{fus}}}{\eta_{\text{plug} \rightarrow \text{plasma}} Q_{\text{fus}}} - P_{\text{BOP}} \quad (9)$$

Here, η_{th} is the thermal efficiency for converting fusion-produced heat to electricity, M_{bl} is a power multiplier due to exothermic reactions as the neutrons are captured in an external blanket, $\eta_{\text{plug} \rightarrow \text{plasma}}$ is the plug-to-plasma efficiency for delivering external heating to the plasma, and P_{BOP} is the power required to operate the balance of plant (i.e., cooling systems, cryogenic systems, etc.). An example of the impact of Q_{fus} on the attainable net electricity for a fusion system producing 1 GW of thermal fusion power (i.e., $P_{\text{fus}} = 1$ GW) is shown in Fig. 4 for various assumptions of η_{th} and $\eta_{\text{plug} \rightarrow \text{plasma}}$ with $M_{\text{bl}} = 1.2$ and $P_{\text{BOP}} = 50$ MW. It is evident that $P_{\text{electricity}}$ drops precipitously for $Q_{\text{fus}} < 15$ in all cases and that there is no significant gain in $P_{\text{electricity}}$ for $Q_{\text{fus}} > 40$ in any of the cases.

Assuming $15 < Q_{\text{fus}} < 40$ is desirable for practical fusion energy, recognizing that the minimum $n_e T_i \tau$ occurs at 14 keV, and using the approximate expression for $\langle \sigma v \rangle_{\text{fus,DT}}$ introduced earlier, practical fusion energy requires achieving the criterion:

$$1.7 \lesssim n_e \tau|_{D-T} (\cdot 10^{20} \text{ m}^{-3} \cdot \text{s}) \lesssim 2.0 \text{ at } T_i = 14 \text{ keV} \quad (10)$$

Fig. 4 Anticipated net electricity production for a 1 GW thermal fusion facility for various assumptions of thermal efficiency η_{th} and plug-to-plasma efficiency $\eta_{plug \rightarrow plasma}$ and $M_{bl} = 1.2$ and $P_{BoP} = 50$ MW.

As is evident from Fig. 1a, slightly off-optimum temperatures will result in a very rapid increase in this criterion.

Different confinement approaches seek to achieve the criterion in Eq. (10) via different approaches, employing a wide range of possible density values. For example, inertial confinement uses high-energy lasers to compress a small pellet to densities approaching 10^{31} m^{-3} , thereby requiring only picosecond-scale confinement times. In contrast, magnetic confinement uses strong magnetic fields to confine the plasma to achieve densities in the range of 10^{20} m^{-3} , leading to confinement requirements on the order of seconds. Other approaches lie in between these extremes.

It should be noted that the equations above assume thermal equilibrium conditions (i.e., systems with Maxwellian distributions of the reacting ions) with equal ion and electron temperatures (i.e., $T_e = T_i$). Note also that the condition in Eq. (10) can, in principle, be relaxed if techniques are employed that drive strongly non-Maxwellian distributions in the reacting ions or utilize systems with $T_i \gg T_e$. While such techniques can significantly increase the average fusion reactivity and thereby reduce the $n_e T_i \tau$ requirement, experience to date has shown that the external power required to produce such distributions is typically quite high, resulting in low Q_{fus} values that are impractical for fusion electricity production.

Magnetic confinement

As noted above, there are multiple potential approaches to achieving practical fusion energy. The most advanced in terms of achieving the necessary conditions is magnetic confinement, which takes advantage of the features of the very hot gas as it approaches fusion conditions. At temperatures relevant to thermonuclear fusion ($> 10 \text{ keV}$), most of the atoms in the system will be ionized to some extent, with the low-charge (i.e., low-Z) atoms fully stripped. As an example, the ionization potential of hydrogen and helium is 13.6 and 24.6 eV, respectively. The ion/electron bath that results is called a plasma, the fourth state of matter. In many respects, the plasma behaves similarly to a gas, diffusing along gradients of density and temperature or through turbulent eddies generated by irregularities in the plasma characteristics.

Deuterium atoms at 10 keV have an average velocity of nearly 700,000 m per second (over 1,500,000 miles per hour). Because of this mobility, effective confinement times without any confining mechanisms are quite short, leading to very low values of the plasma confinement τ and a much more severe requirement on the necessary plasma pressure $n_e T_i$. As importantly, any contact of the very hot plasma with the walls of the confinement chamber will cause rapid cooling of the plasma, thereby eliminating access to fusion-like temperatures. Hence, standard confinement methods as might be used for high pressure gases are not possible.

Fortunately, nature has provided a solution to this challenge in the form of the Lorentz force that acts on charged particles moving in a magnetic field. This force is given by (Jackson, 1975):

$$\vec{F}_{+/-} = \vec{v} \times \vec{B} \quad (11)$$

where the $\times$ operator indicates the cross product. As depicted in Fig. 5, this force causes the charged particle to accelerate in a direction both perpendicular to its own motion $\vec{v}$ and that of the magnetic field $\vec{B}$ it is passing through.

Fig. 5 Trajectory (blue) of a charged particle in the presence of a magnetic field $\vec{B}$ (red) due to the Lorentz force. As the magnetic field is doubled (right hand figure), the Larmor radius r_L decreases by a factor of two.

Because the force acts perpendicularly to the magnetic field line, the velocity in the direction of $\vec{B}$ is unchanged (i.e., $v_{\parallel}$ is unchanged). In the perpendicular direction, $\vec{F}_{+/-}$ is a centripetal (i.e., acting radially inward) force, producing a circular motion of the particle around the field line. The net effect is a spiral-like motion with the charged particle's trajectory being tied closely to that of the trajectory of the magnetic field line. Such a trajectory is shown in Fig. 5. The radial extent of the particle motion is inversely proportional to the magnetic field strength ($r_L = mv_{\perp}/ZeB$); hence, the stronger the magnetic field the more closely the particle's trajectory is tied to that of the magnetic field line.

This effect is the reason why the Aurora Borealis and Aurora Australis are only evident in polar regions as high-energy electrons ejected by the sun encounter the magnetic field lines generated by the Earth and are directed along those field lines to the polar regions. There, they collide with the Earth's atmosphere, generating fascinating light spectacles.

Magnetic fusion confinement systems attempt to generate sufficient confinement by taking advantage of this feature by devising magnetic field configurations that direct particles away from the walls of the confinement chamber. These configurations are typically produced by strong electromagnetic coils located outside the confinement chamber, capable of producing magnetic field strengths in the several Tesla range. For reference, the Earth's magnetic field is $< 10^{-4}$ T. Two types of magnetic confinement systems have been developed and tested—closed and open. The basics of each concept are described next.

Toroidal (closed) confinement

Closed systems attempt to close the magnetic field lines on themselves, typically using a doughnut-like (i.e., toroidal) geometry—though other geometries have been conceived and tested. In its simplest form conceptually, such a system is configured such that the magnetic field lines travel around the doughnut (i.e., torus) the long way, directing particle trajectories in a similar manner. Practically, several physics considerations impose a requirement that the magnetic field lines must also wrap around the torus the short way, creating a magnetic field structure that wraps the short way around the torus (known as the poloidal direction) as it traverses the full circumference of the torus (known as the toroidal direction).

The “pitch” of the field line as it makes this transit impacts a number of physics effects. As with a rope, increasing the twist (i.e., higher pitch) of the magnetic field lines increases the strength of the magnetic field bundle, enabling the confinement of plasmas with higher pressure. Accordingly, the variation of the magnetic pitch is a primary distinguishing feature of the range of closed magnetic confinement approaches (Galvao, 2020). Some approaches have low pitch throughout, others have low pitch in the center of the plasma rising towards the edge, others have high pitch in the center decreasing towards the edge, while others have flat pitch profiles.

Many, many toroidal confinement concepts have been evaluated throughout the history of magnetic fusion. The most advanced of these is the tokamak, originally developed in Russia and shown subsequently to have very good plasma confinement properties. The tokamak magnetic field structure is generated by a set of toroidal field magnets that create a strong toroidal field and a toroidal plasma current that generates the poloidal magnetic field. The toroidal field is typically much larger than the poloidal magnetic field with a pitch profile that increases from the core to the edge. The spherical tokamak is a variation of the standard tokamak with similar physics features.

The next most advanced configuration is the stellarator with a magnetic configuration that is defined by a set of 3D magnetic coils surrounding the device. There are many different forms of stellarator geometries but they are all primarily determined by the choice of magnetic coils (i.e., very little additional magnetic field is provided by internal plasma currents). This variability leads to many different magnetic pitch profiles, each having benefits as well as disadvantages.

Other toroidal confinement systems include:

- The spheromak has a very similar magnetic geometry as a tokamak but arrives at this state through dynamic formation of the plasma that drive toroidal and poloidal currents to form the magnetic field structure. This eliminates the need for toroidal magnetic field coils.
- The reversed field pinch is similar to tokamak magnetic geometry but with a much smaller toroidal field. As with the spheromak, these fields are primarily generated by currents flowing in the plasma. The driven toroidal plasma current is of sufficient strength that the toroidal magnetic field reverses direction, leading to a significantly different pitch profile from tokamaks or spheromaks.

Linear (Open) confinement systems

Open magnetic confinement systems take advantage of an additional feature of charged particle motion in magnetic fields. Because the Lorentz force is a centripetal force (i.e., the force only works in the radial direction), the angular momentum ($L = mv_{\perp}R$) is conserved. Using the expression for the Larmor radius (i.e., $r_L = mv_{\perp}/ZeB$), the perpendicular kinetic energy can be expressed as $E_{\perp} = mv_{\perp}^2/2 = \mu B$ where $\mu = ZeL/2m$. Since the kinetic energy ($KE = mv_{\parallel}^2/2 + mv_{\perp}^2/2$) of the particle is also conserved, the velocity along the field line can then be written as (Post, 2011):

$$v_{\parallel}^2(s) = \frac{2}{m}[KE - \mu B(s)] \quad (12)$$

Here, s represents the distance along a field line. Hence, as a particle moves into a region of stronger magnetic field, the velocity in the direction of the field line $v_{\parallel}$ must decrease and if the magnetic field becomes large enough, the particle will be reflected (i.e., $v_{\parallel}$ changes sign).

Taking advantage of this feature, linear confinement systems rely on this “mirror” effect to confine plasmas in configurations in which the magnetic field lines do not close on themselves. As one might expect from Eq. (12), not all particles are confined. The exact set of confined particles is given by $v_{\perp}/v > \sqrt{1/\rho_{\text{mirror}}}$. Here $\rho_{\text{mirror}} = B_{\text{max}}/B_{\text{min}}$ is the mirror ratio and B_{max} and B_{min} are the maximum and minimum magnetic field strength, respectively. Hence, by increasing ρ_{mirror} , one can increase the fraction of particles that are confined. An interesting feature of linear systems is that this confined fraction does not change as the plasma becomes hotter, in principle allowing operation up to fusion-relevant temperatures.

Similar to their toroidal confinement counterparts, many types of linear systems have been conceptualized and studied. The most notable of these are:

- Mirror devices that utilize strong magnetic field coils at either end of a cylinder to confine the plasma. Because of free-streaming losses out the ends of the cylinder, some variations use complicated magnetic field structures in these regions to improve overall confinement.
- Field-reverse configurations (FRCs) address the end-loss issue by dynamically generating internal currents in the plasma that results in regions of closed field lines, essentially producing a toroidal plasma within a linear system.
- Magnetic cusps use strong magnetic field coils to generate magnetic wells to confine the electrons and rely on electrostatic confinement of the ions within these wells.

To date, none of these have delivered performance on par with tokamaks or stellarators.

Stability, confinement, and fusion performance

The maximum pressure that can be sustained in a magnetic confinement system is dependent on the applied magnetic field with the ratio of the kinetic pressure to the magnetic field pressure:

$$\beta = \frac{\text{Kinetic pressure}}{\text{Magnetic pressure}} = \frac{n_e T_e + n_{i,1} T_i + n_{i,2} T_i}{B^2/2\mu_0} \quad (13)$$

serving as a critical parameter in the stability of the system. The attainable β depends on details of the particular magnetic configuration and can range from a few % in some confinement systems to near unity in others.

Revisiting the expression for sustaining a fusion plasma, one finds that the self-sustainment expression can be written as:

$$\beta \tau (\% \cdot s) > \frac{3\mu_0 T_i^2 \varepsilon_m^2 (1 + \delta_{12})}{4 \langle \sigma v \rangle_{fus} E_{fus}^{+-} B^2 Z_1 Z_2} \left(\frac{Q_{fus}}{Q_{fus} + \gamma_{fus}} \right) * 100 \quad (14)$$

Immediately, one can see that increasing the magnetic field strength is very beneficial in reducing the $\beta \tau$ requirement. Eq. (14) also offers other possibilities for reducing the required $\beta \tau$ through operation with $T_i \gg T_e$ (i.e., $f_T \ll 1$) or increasing $\langle \sigma v \rangle_{fus}$ through tailoring of the ion distribution (i.e., driving ions to high energies so that they are more likely to fuse).

It should be realized that β is constrained by the magnetic configuration in consideration. Although the β constraint does not introduce severe demands on systems utilizing the D-T reaction, it does introduce challenges for other fusion reactions. As shown in Fig. 1b, the minimum $\beta \tau$ for the D-T reaction is approximately 10%-s at 5 T, decreasing to 2.5%-s at 10 T. The situation is considerably different for the other fusion reactions, with the minimum $\beta \tau$ being above 100%-s for D-He³ and 1000%-s for p-B¹¹ at 5 T. For these reactions, systems that are limited to $\beta < 5\%$ (or even $\beta < 10\%$) will have stringent (and possibly impractical) demands on the confinement requirement.

Looking more specifically at the D-T reaction ($Z_1 = Z_2 = 1$, $\gamma_{fus} = 5$, $E_{fus}^{+-} = 3.5 \text{ MeV}$), assuming $T_i = T_e$, and using the expression introduced above for $\langle \sigma v \rangle_{fus}$ one finds:

$$\beta \tau (\% \cdot s)|_{DT} \gtrsim \frac{250}{B^2} \left(\frac{Q_{fus}}{Q_{fus} + 5} \right) \quad (15)$$

This equation is very useful in defining the challenge for fusion energy production from the plasma performance perspective as the right-hand side contains the output requirements (Q_{fus}) and technological constraints (B) of the system while the left-hand side only involves plasma performance metrics (β , τ). Several tradeoffs are evident. Lower fusion gain requirements or higher magnetic field can reduce the physics performance requirements. In contrast, higher physics performance could reduce the demands on the necessary magnetic field and enable higher values of fusion gain.

The various confinement systems outlined above attempt to exploit their intrinsic advantages to satisfy this requirement. For example, tokamaks take advantage of intrinsically higher confinement than other approaches (but suffer somewhat due to the minimum heating power set by the need drive the plasma current by external sources). Stellarators take advantage of a reduced need for external current drive power, thereby increasing the attainable Q_{fus} , reversed field pinch take advantage of a reduced requirement for magnetic field strength B and access to high β , etc. It is also important to note that all of the parameters in Eq. (15) have practical limits (e.g., β cannot exceed unity, τ cannot be arbitrarily high, B is limited by magnet technology, and Q_{fus} must be high enough to guarantee net electricity output).

In fact, the available combinations of β , τ , B , and Q_{fus} is somewhat limited. Because any improvement in the controllable stability (β) and confinement (τ) will open up the attainable operating space, we will take a look at these in the next few sections, followed by a brief section on the attainable magnetic field.

Plasma stability

As noted above, the plasma β is a critical parameter in determining the sustainable plasma pressure of a magnetic confinement system. This arises from the combination of the lowest order momentum balance equation:

$$\nabla p = J \times B \quad (16)$$

and Ampere's Law:

$$\mu_0 J = \nabla \times B \quad (17)$$

which upon combining and some arithmetic becomes:

$$\nabla(p + B^2/2\mu_0) \equiv \nabla(B^2/2\mu_0(1 + \beta)) = \frac{1}{\mu_0}(B \cdot \nabla)B \quad (18)$$

Magnetic confinement approaches (in which the magnetic field is utilized to confine the plasma and its associated pressure) have $B^2/2\mu_0 > p$ (or equivalently $\beta < 1$). More typically, $\beta \ll 1$. In Eq. (18), ∇p represents the kinetic pressure gradient, $\nabla B^2/2\mu_0$ represents the magnetic pressure gradient, and the RHS is the magnetic field tension force that acts to straighten the magnetic field lines (akin to the force on an arrow when a bow is stretched).

Note that even at zero pressure (or equivalently $\beta = 0$), there can be a magnetic field tension force depending on the choice of magnetic configuration. As ∇p is increased, the tension force increases due to the plasma pushing on the magnetic field lines. If the magnetic configuration can handle this increase, the system is stable. However, if ∇p increases beyond a point in which the system can supply additional magnetic tension, the magnetic field lines can rupture, causing rapid loss of plasma confinement. This is akin to pulling the string on a bow too far such that it breaks.

The maximum β a system can achieve therefore measures the relative amount of additional tension due to kinetic pressure that a system can sustain before loss of stability. Note that because $\beta \propto 1/B^2$, systems with higher field that are otherwise identical can sustain much larger increases in kinetic pressure.

As noted above, there are three main types of instability limit that govern the envelope of attainable β in magnetic confinement systems. These include the equilibrium limit, the "ballooning" instability limit, and the "kink" instability limit. The equilibrium limit is fundamental to a confinement system and determines whether or not the magnetic configuration itself is fundamentally stable or not. Typically, the equilibrium limit is not overly sensitive to β but this stability requirement must always be met at all values of β .

The ballooning instability limit occurs when ∇p increases to a point that the total pressure gradient locally exceeds the restoring force of the magnetic field lines. The name comes from the finger-like structures that form during the instability with features similar to the elongations formed in a balloon when it is squeezed. Ballooning instabilities are typically small in spatial scale, and therefore do not cause a complete loss of the confined plasma. However, they do reduce confinement (sometimes significantly), thereby limiting both the attainable β and τ . More details on this type of instability can be found in (Lao, 2021).

The kink instability limit, at its most fundamental level, occurs when a plasma column is distorted in such a way that magnetic pressure increases on one side of the column and decreases on the other, further amplifying the distortion. In essence, the tension on the RHS of Eq. (18) increases on one side of the column (becoming more stable) but decreases on the other side of the column (becoming more unstable), leading to an instability. This is similar to what occurs when twisting a rubber band to the point and suddenly knots start to occur due to the inability of the rubber bands to maintain the original structure. These instabilities are generally fairly large in spatial scale and therefore pose a severe risk to overall plasma operation. As such, this instability limit

generally serves as the primary limit on the attainable/sustainable β in many toroidal systems. For some devices, this limit is very low (e.g., $\beta < 1\%$ in linear devices), in others modest (e.g., $\beta < 10\%$ in tokamaks/stellarators), and others very high (e.g., $\beta \sim 100\%$ in reversed field pinches). More details on this type of instability can be found in (Lao, 2021).

Plasma transport and confinement

As noted in the introduction to this section, collision-less ions and electrons are “confined” to magnetic field lines through the Lorentz force, resulting in orbital motion with a characteristic gyro-frequency $\Omega = ZeB/m$ and radius $r_L = mv_{\perp}/ZeB$ with any transport off these field lines occurring only due to second order effects. These second order effects can have non-trivial consequences. For example, in a purely toroidal magnetic field configuration (i.e., no pitch of the field lines), particles will inevitably drift upward/downward depending on their charge. This effect is one of the primary reasons pitch of the field lines is required in any toroidal confinement device.

Collisions are another source of transport. Collisions can potentially knock particles off their collisionless orbits. While still generally confined on another field line and associated orbit, these collisions lead to effective transport.

Bohm transport

The degree of this effect can be estimated using the general formula for diffusion $D = \Delta x^2 / \Delta t$ where Δx is the characteristic step size due to collisions and Δt is the characteristic time between collisions. If one assumes that the step size is the distance a thermal particle would travel during a single particle orbit, $\Delta x = v_{th}/\Omega$ where $v_{th} \propto (T/m)^{1/2}$ is the thermal velocity and that the characteristic time step is given by the inverse gyro-frequency $\Delta t = 1/\Omega$, one arrives at the so-called Bohm diffusion coefficient with the sensitivities:

$$D_{Bohm} \propto \frac{T}{B} \quad (19)$$

Generally, one finds that projections with D_{Bohm} are very pessimistic for achieving sufficient conditions for fusion production due to the strong temperature dependence. Fortunately, experimentally observed transport rates in toroidal confinement systems are much lower than those predicted by D_{Bohm} . This overestimate is due to the fact that the collision time is much larger than the time for a particle to complete a single orbit (i.e., $\Delta t_{coll} \gg 1/\Omega$).

Classical transport

The “classical” diffusion rate can be estimated by assuming that the characteristic time step is the inverse collision rate $\Delta t = 1/\nu_{coll}$. Here, $\nu_{coll} \propto n/T^{3/2}$ is the collision frequency. These simple assumptions lead to a “classical” diffusion coefficient with the sensitivities:

$$D_{cl} \propto \frac{n}{B^2 T^{1/2}} \quad (20)$$

The inverse dependences in B and T here provided researchers with early hope on the prospects for fusion energy. However, experiments soon demonstrated that D_{cl} significantly underestimated the observed transport. This is primarily due to the fact that the assumed spatial excursions in this model only include first order orbit effects (i.e., motion around the field line) and neglect important second order orbit effects as well as collective transport due to turbulence and other anomalous effects. These effects are explored next.

“Neoclassical” transport

As noted previously, all toroidal confinement systems have the feature that a magnetic field line has a trajectory that travels both poloidally and toroidally. A further standard feature of toroidal confinement systems is that the toroidal magnetic field strength varies as $B = 1/R$. Hence, a particle will experience a range of magnetic field strengths as it follows the field line. Due to the trapping effect introduced earlier, this can lead to certain particles being reflected (i.e., $v_{\parallel}$ changing sign). When this occurs, the “trapped” particle is forced to make an excursion off that field line, thereby increasing the characteristic step size Δx . Consideration of this new type of orbit requires detailed calculations of the orbit classes and evaluation of the anticipated excursions of those orbit classes in the time between collisions. These effects are called neoclassical transport. The parametric dependence of D_{neo} derived within neoclassical transport analysis is a fairly complex set of formulae dependent on the magnetic topology and collisionality of the particular system involved. Although these calculations typically predict $D_{neo} > D_{cl}$ and hence resolve some of differences with experimental observations, detailed comparisons with neoclassical theory have generally shown that D_{neo} also underestimates observed transport rates, though in some cases consistency has been found.

Turbulent transport

Another effect that increases the effective transport step Δx is turbulent-driven transport. As in any fluid, the flow of energy and particles through the system (and the associated gradients), if large enough, has the potential to produce turbulence. This turbulence can drive transport through correlated fluctuations of the plasma density, temperature, electrostatic potential, and magnetic fields. For most cases to date, the primary turbulence mechanism is due to electrostatic fluctuations and is referred to as drift-wave turbulence. Mathematically, drift waves are small-scale-length solutions to the dispersion relation for waves propagating in a magnetic confinement system. These waves introduce period variations in the electrostatic potential (or equivalently the electric field E) and an associated periodic variation in the drift velocity $v_{dr} = E \times B/B^2$, leading to circulating, small-scale turbulent cells in the plasma.

Turbulent modes take many different forms. Some are driven by the density gradient, others by the temperature gradient. Some primarily cause particle transport, others energy transport. Some primarily affect electron transport, others ion transport, and still others both. Some act on very small spatial scales, others on extended spatial scales. Therefore, the net effect on overall transport is difficult to parameterize easily.

This is further complicated by the fact that these turbulent structures can be sheared apart by a variety of dynamics. If the background plasma is moving at different speeds on one side of the structure relative to the other side, the turbulence can be sheared apart, thereby reducing the net transport. A similar effect can happen if the field line pitch varies across the turbulent eddy. A further complication is that the turbulence itself can generate flows that act to tear apart the turbulence. Hence, predicting the level of transport due to turbulence, characterized by D_{turb} , requires sophisticated numerical models that capture the generation of the turbulence, the generation of flows by the turbulence, and finally taking all this into consideration, the resultant magnitude of the turbulence-driven transport. These models predict transport rates, D_{turb} , that are, in general, significantly above D_{neo} but much smaller than D_{Bohm} . Many experiments have shown consistency between the predicted transport rates and those observed as well as consistency with measurements of the underlying turbulence levels. A much more comprehensive overview of the turbulent-driven transport can be found in (Jenko, 2021).

Ultimately, the effective transport is a combination of both collisional and turbulent transport. Because these effects tend to occur on different spatial scales, the overall transport rate can be written as $D_{tot} = D_{neo} + D_{turb}$. In most cases, $D_{turb} \gg D_{neo}$; however, in cases where turbulence is suppressed through the means described above, D_{neo} provides a floor on the overall transport rate.

Overall confinement

Because of the complications described in the previous section, the overall confinement τ_E is very situation specific and can vary over a large range as key parameters are adjusted. For this reason, the fusion community has developed scalings based on experimental observations that seek to capture the major dependences of confinement on the underlying parameters. This is typically done by performing a regression analysis of an experimental data base on an identified set of engineering parameters. These engineering parameters are easily quantified and chosen to be representative of the major features of any system being considered or designed. A typical list might include toroidal field B , plasma current I , density n , heating power P , device size R , plasma shaping parameters for elongation κ and inverse aspect ratio $\epsilon = a/R$, and isotope mass M . A regression analysis of these parameters would take the form (Yushmanov et al., 1990):

$$\tau_E = C B^{\alpha_B} I^{\alpha_I} n^{\alpha_n} P^{\alpha_P} R^{\alpha_R} \kappa^{\alpha_\kappa} \epsilon^{\alpha_\epsilon} M^{\alpha_M} \quad (21)$$

As we will see, this list is somewhat specific to tokamak confinement and new parameters may be needed to fully parameterize confinement in other types of systems.

A regression analysis of the form given in Eq. (21) requires a sufficient dataset with representative variations in all the parameters shown. In general, data from multiple devices is required to provide a sufficient basis for reasonably accurate projections of confinement using this approach. To date, only two types of magnetic confinement systems have such a range of devices: tokamaks and stellarators. To illustrate this approach to projecting confinement, we will use the tokamak and in particular, the confinement scalings that have been developed to inform the design of ITER.

In addition to a sufficient range, the data must also be well conditioned to be representative of the types of operating conditions expected in ITER. Even with such conditioning, the database for tokamaks is quite extensive in the parameters of Eq. (21) as shown in Table 2. Applying the regression analysis of Eq. (21), one finds a reasonably good fit over the full data range as is shown in Fig. 6.

Table 2 Range of data in tokamak H-mode database and scaling exponents for the ITER H98y2 (ITER Physics Expert Group on Confinement and Transport, 1999) and DS03 scalings.

	B (T)	I (MA)	n ($10^{20} m^{-3}$)	P (MW)	R (m)	κ	ϵ	M
Minimum in database	1.05	0.14	1.21	0.18	1.29	0.93	0.16	1.0
Maximum in database	3.72	5.13	11.7	18.2	2.93	2.07	0.41	2.0
α_x (H98y2)	0.15	0.93	0.41	−0.69	1.97	0.78	0.58	0.19
α_x (DS03)	0.30	0.75	0.32	−0.47	2.09	0.88	0.84	0.0

Fig. 6 Comparison of the experimentally measured thermal confinement time in tokamaks with the empirical scaling ITER H98y2 (Wagner, 2013).

The exponents in Eq. (21) for this fit are shown in Table 2 and project to $\tau_E = 3.2$ s for the design values of ITER. Combined with ITER design values of $\beta = 2\%$, $B = 5.3$ T, and $Q_{fus} = 10$, one can see that the criteria for self-sustained fusion operation given by Eq. (15) is satisfied.

A separate method to develop a confinement scaling is to utilize a wind-tunnel approach that first develops scalings of how confinement varies with key non-dimensional physics variables (as opposed to engineering variables). These parameterizations are then utilized to construct an overall confinement scaling that captures the dependence on engineering variables. In principle, there are many dimensionless physics parameters. The challenge is to identify those parameters that represent key aspects of the underlying physics phenomena.

From the discussion above on transport effects, the key physics effects are related to the characteristic orbit size and how often particles collide. Another key factor in the overall system description is any change in tension the field line experiences as particles move through or cause fluctuations within the system. A final consideration is the relative role of Coulomb interactions on the particle dynamics. Identifying non-dimensional physics variables that represent these physics effects then allows one to construct physics-based scalings in smaller devices that can be used reliably for projections to larger systems. This is akin to the testing of new automobile and plane designs in wind tunnels where care has been taken to ensure the non-dimensional variables in those laboratory tests are identical to those experienced in real-time situations.

The first scientist to do this for toroidal magnetic systems was Boris Kadomtsev (Kadomtsev, 1975) who identified four plasma physics parameters:

- the ratio of the gyroradius to the device size (ρ^*), which provides quantification of the characteristic orbit size relative to the size of the confining system;
- the collision frequency relative to the orbit bounce frequency (ν^*), which reflects the relative impact of collisions in modifying orbit trajectories;
- the plasma β [defined in Eq. (13)], which characterizes the relative tension that the magnetic fields within the system are under and therefore an indication of the relative impact of kinetic vs electromagnetic effects;
- and the total number of particles in a Debye sphere (N_D), which quantifies the relative impact of single-particle Coulomb interactions vs collective effects.

Combining with other non-dimensional parameters that are the ratios of like quantities such as the inverse aspect ratio $\epsilon = a/R$, the safety factor $q = eB_T/B_p$, and m_e/m_i , one can arrive at a set of parameters that describe any toroidal confinement plasma system. This can even be extended further by including additional parameters like the ratio of the plasma height to width (κ), separate ion and electron temperatures T_e/T_i , more than one ion charge state Z_{eff} , and plasma rotation (Mach number).

Further work by Connor and Taylor (Connor and Taylor, 1977) on scale invariance of the equations that govern plasma dynamics showed that N_D plays a negligible role in the scale invariance in the governing equations due to its vast difference in magnitude relative to the other parameters. In other words, an enormous change in N_D would be required to have an impact on the underlying physics that is comparable to the impact caused by small changes in the other variables.

This leaves ρ^* , β , and ν^* as the primary non-dimensional physics variables. This work also confirmed that ρ^* serves as a good proxy for electrostatic effects on transport, β a proxy for magnetic effects, and ν^* a proxy for collisional effects. The popularity of using these variables to describe plasma confinement is largely due to the transparent relationship between the underlying physical phenomena and these parameters.

On this basis, one can carry out experiments to determine how transport scales with each of these variables. This is typically done by varying one of the variables *while* holding all the other non-dimensional parameters approximately constant through appropriate choices in the underlying engineering parameters such as magnetic field strength, input power, and plasma density. While studies on different devices (or combination of devices) have revealed a range of variations, a generally accepted set of scalings are: $\Omega\tau_E \propto \rho^*{}^{-3}$, $\Omega\tau_E \propto \beta^0$, and $\Omega\tau_E \propto \nu^*{}^{-0.3}$ (Petty, 2008). Note that $\Omega\tau_E$, where Ω is the gyrofrequency introduced earlier, is used here as a “normalized,” non-dimensional confinement time. Its use results from applying the principles of scale invariance introduced above to the governing equations for plasma transport.

The above set of variations with ρ^* , β , and ν^* is broadly consistent with the theoretical expectations that the effect of small-spatial-scale electrostatic turbulence will diminish as the device size increases relative to the gyroradius (strong dependence on ρ^*), the limited role of electromagnetic fluctuations (very small dependence on β), and the modest favorable impact of reduced collisionality (modest dependence on ν^*). Because of the independence of these variations, one can then form an overall normalized confinement of the form:

$$\Omega\tau_E \propto \rho_*^{-3} \beta^0 \nu_*^{-0.3} F(\dots) \quad (22)$$

where $F(\dots)$ represents the variation due to other dimensionless parameters.

Because ρ^* , β , and ν^* (and the other parameters in F above) are themselves combinations of the engineering variables of Eq. (21), one can then recast Eq. (22) in the form of Eq. (21) to reveal the dependence on the engineering variables. Such an exercise yields the DSO3 exponents shown in Table 2. Note that the dependence on the engineering parameters are somewhat similar but have important differences (especially with regard to the input power), potentially leading to different projections than the fully empirical scaling. As an example, the projection for ITER design values using the DSO3 scaling is $\tau_E = 4.7$ s, much more favorable than the empirical scaling shown in Fig. 6.

Magnet technology

As noted in the discussion of Eq. (15), the ability to increase the magnetic field can be utilized to reduce the requirements on stability (β) and confinement (τ). This has been well recognized in fusion research since its onset and has served as a major driver in the worldwide development of large-scale, superconducting magnet technology. Substantial qualitative and quantitative progress has been achieved in magnet technology for fusion over the past 25 years, systematically addressing a range of limitations and increasing the operating regime over which long-pulse, high-field operation can be obtained. These limitations take on different forms depending on the magnet technology but generally fall into three categories: internal heating of the coil; current density limits; and mechanical stress limits. For superconducting magnets, the internal heating limitation is replaced by limitations on the maximum operating temperature and magnetic field for superconducting operation.

Fusion reactor applications typically require toroidal magnetic fields of > 5 T and demand long-pulse operation of the magnet. The magnetic field requirement translates into significant current density within the magnet and the potential for significant internal heating of the magnet due to its intrinsic resistance to current flow. This resistive process (known as Joule heating or Ohmic heating) scales as $P_{Ohmic} \propto I^2 R \propto J^2 A^2 R$ where R is the resistance of the conductor, J is the current density in the conductor, and A is the area of the conductor. This heat generation is problematic as more electrical power is required to produce the same current in the coil and significant cooling systems are required to dissipate the heat sufficiently to protect the coil from thermal damage. For these reasons, even the use of low-resistance conductors such as copper at very high current (or equivalently current densities) is precluded for steady-state operation of fusion magnets.

This realization led to the early adoption by fusion system designers of superconducting magnet technology. Superconductivity is the phenomena that occurs when a material is cooled below a critical temperature at which its resistance suddenly disappears. Superconductivity was first observed in 1911 by Heike Kamerlingh Onnes (Onnes, 1912), for which he won a Nobel Prize in physics a few years later. Early attempts to develop magnets based on this phenomenon were unsuccessful, and it wasn't until the mid-1950s that electromagnets (using niobium) were successfully produced; however, these magnets still had serious limitations in current density and in the magnetic field at which high current density could be maintained. In the early 1960s, a team from Bell Labs developed and demonstrated simultaneous operation at high current density (10^5 A/cm²) and high magnetic field (8.8 T) of a Nb₃Sn conductor (Kunzler et al., 1961). Since this demonstration, various alloys of niobium have been successfully developed, eventually leading to the adaptation of Nb₃Sn and NbTi conductors in the superconducting magnets for ITER and other planned fusion systems.

Although the niobium-based superconducting magnets have opened up a large range of potential fusion applications (Table 3), they have two limitations: the magnet must be maintained below a critical temperature T_c (typically near 4.2 K implying significant refrigeration cost) and the maximum operating magnetic field in which high current density is possible is limited to < 20 T (thereby limiting the attainable magnetic field for confinement purposes). Another Nobel Prize discovery in the

Table 3 Properties of potential superconducting magnet materials for fusion applications.

Superconducting material	Critical temperature T_c (K)	Critical magnetic field (T) at 4.2 K	Critical current density at 15 T (4.2 K)
NbTi	10	15	0
Nb ₃ Sn (ITER)	18	24	500
Nb ₃ Sn (Internal Sn)	18	24	1000
Bi ₂ Sr ₂ CaCu ₂ O ₈ (Bi 2212)	96	>40	1500
Bi ₂ Sr ₂ CaCu ₂ O ₁₀ (Bi 2223)	108	>40	350
YBa ₂ Cu ₃ O ₇ (YBCO/REBCO)	92	>40	3500

mid-1980s (Bednorz and Muller, 1986) that a certain set of ceramics (known as copper oxides or cuprates) exhibit a superconductivity transition at much higher temperatures has opened up the operating space for superconducting magnets even further. The most advanced of these high temperature superconducting (HTS) materials can operate with $T_c \sim 110$ K and at magnetic fields exceeding 40 T (theory suggests much higher fields are possible). The critical temperature, magnetic field, and current density for possible superconducting materials is provided in Table 1.

As noted previously, the ITER magnet design (Mitchell et al., 2008) utilizes NbTi for modest field applications (poloidal field coils with maximum fields less than 6 T) and Nb₃Sn for the high-field magnets (toroidal field coils and the central solenoid with maximum fields less than 13 T). For typical fusion systems, these maximum magnetic fields translate into 5–7 T fields in the plasma. New designs are emerging within the fusion community worldwide that take advantage of HTS magnets (Sorbom et al., 2015). These designs typically have maximum magnetic fields at the coils around 23 T, translating to ~ 12 T in the plasma. At present, the manufacturability of large-scale NbTi and Nb₃Sn magnets has been demonstrated by the ITER project with the production of sufficient lengths of NbTi and Nb₃Sn strand demonstrated by multiple companies. Several private firms are now pursuing such a demonstration of REBCO-based magnets.

While the focus of this development has been on taking advantage of the higher critical magnetic field of these materials, there are significant benefits derived from being able to operate HTS magnets at higher temperature and higher current density. Higher temperature operation will reduce the refrigeration system operating costs and also enables the possibility of jointed coils, which could significantly improve the maintainability of the fusion system. Higher current density operation potentially translates to a smaller magnet. However, there are a few considerations that could limit this. Firstly, higher field operation will inevitably need more mechanical structure to react against the electromagnetic forces. Because these forces increase as B^2 , significant amounts of support structure must be added as the field is increased. Secondly, the system must always be designed to withstand “quenching” (loss of superconductivity) of the magnet. This effect typically limits the overall current density during the quench phase, resulting in the need to provide additional conducting material in the design to keep the magnet from overheating during the quench event. For these reasons, the full capability of REBCO-based magnets may not be realizable in toroidal confinement systems, and a full systems analysis is required to assess the available operating space.

Magnetic confinement configurations

As discussed in the previous two chapters, one of the most basic requirements for the development of fusion reactors is to confine plasmas with temperatures over 100 million degrees kelvin. This condition requires minimizing the contact between the charged particles and surrounding material walls of the vacuum chamber, inside which the plasma is generated. Since the dawn of fusion research, it became clear that an obvious way to perform this task was to use properly shaped magnetic fields to trap the charged particles. Several magnetic field configurations have been proposed for this purpose and, in this chapter, the main ones that have been developed, and are currently employed in magnetic field fusion research, are discussed.

Magnetic confinement basics

Three physics processes play a basic role regarding equilibrium, stability, and energy transport in magnetically confined plasmas: (i) particle drifts, (ii) macroscopic stability, and (iii) anomalous (i.e., non-collisional) particle and energy transport.

The drift effect can be easily understood by examining the motion of charged particles, let us say of species α , mass m_α and charge q_α , in a uniform magnetic field $\mathbf{B}$ and in the presence of a constant force $\mathbf{F}_\alpha$ (see Chapter 2 in Bittencourt, 2004). Considering first the case without an external force, the motion perpendicular to the magnetic field is restrained to circular orbits, with radius of gyration given by $\rho_\alpha = v_{\alpha\perp}/\omega_{c\alpha}$. Here, $v_{\alpha\perp}$ is the perpendicular component of the particle's velocity and $\omega_{c\alpha} = q_\alpha|\mathbf{B}|/m_\alpha$ is its cyclotron frequency. In the direction parallel to the magnetic field, however, the particle motion is unconstrained, and the parallel component of its velocity, $v_{\alpha\parallel}$, can have any arbitrary value. The resulting orbit becomes a helix winding around a magnetic field line and the instantaneous center of cyclotron motion is called the orbit's guiding center. Considering now the effect of a constant force over the gyromotion perpendicular to the magnetic field, the particle is accelerated when it moves in the direction of $\mathbf{F}_\alpha$ and decelerated when it moves against it. Therefore, it has a larger value of the perpendicular velocity $v_{\alpha\perp}$ at the end of the speed up phase and a smaller one in the end of the slow down phase. This makes the gyroradius ρ_α larger at the end of the former phase and smaller at the end of the latter, so that the orbits do not close circularly anymore in the plane perpendicular to the magnetic field. They become cycloids that displace sideways perpendicular to both $\mathbf{F}_\alpha$ and $\mathbf{B}$, corresponding to a motion of the guiding center with a drift velocity given by

$$\mathbf{v}_{D\alpha} = \frac{1}{q_\alpha} \frac{\mathbf{F}_\alpha \times \mathbf{B}}{B^2} \quad (1)$$

Since electrons and ions gyrate in opposite directions around a magnetic field line, they also drift in opposite directions, unless the external force is due to an electric field $\mathbf{E}$. In this particular case, since electrons are accelerated while moving against $\mathbf{E}$, the phases of increasing and decreasing perpendicular velocity reverse, causing them to drift in the same direction as the ions. This can be seen by the cancellation of charge in Eq. (1) for the particular case in which $\mathbf{F}_\alpha = q_\alpha\mathbf{E}$.

The equilibrium of magnetically confined plasmas is basically described by the balance between plasma pressure gradient and Lorentz forces, i.e., $\nabla p = \mathbf{J} \times \mathbf{B}$, where $\mathbf{J}$ is the current density. The macroscopic stability, however, is somewhat more difficult to explain in simple terms. From the equilibrium equation, it can be predicted that instability sources are mainly associated to pressure gradients and current density perturbations, to the curvature of magnetic field lines, and to spatial anisotropies. Despite this difficulty, some simple models can be explored to elucidate the basic physical mechanisms. One of such a simple models is that of a cylindrical plasma column of sharp boundary. In this model, the plasma is permeated by an uniform and constant longitudinal magnetic field $\mathbf{B} = B_z\hat{\mathbf{e}}_z$, produced by external coils, it has a constant plasma pressure p_0 and a surface current density $\mathbf{K} = K_a\hat{\mathbf{e}}_\phi$ at the sharp boundary (see Chapter 13 in Bittencourt, 2004). The magnetic field outside of the plasma column generated by the

plasma current is given by $B_p = B_\theta(r)\hat{e}_\theta = aB_a/r\hat{e}_\theta$, where $B_a = B_\theta(a) = \mu_0 K_a$ and a is the radius of the plasma column. The plasma equilibrium equation, integrated over the sharp plasma boundary, imposes that

$$p_0 = \frac{B_a^2}{2\mu_0} \quad (2)$$

Let us now assume that the sharp plasma boundary is perturbed as indicated in Fig. 1. Considering the plasma as an incompressible, ideally conducting fluid, one has that, in the regions where the column radius shrinks, the magnetic pressure due to the field generated by the plasma current increases and it decreases in the regions where the column inflates. Since the plasma pressure is constant, pressure imbalance favors the perturbation to keep further growing. However, the longitudinal field frozen in the plasma also exerts a magnetic pressure and reacts to compression and expansion. The variation of the magnetic pressure due to the longitudinal field associated with the perturbation can be calculated by considering the constancy of the magnetic flux $\phi_m = \pi r^2 B_z$ in the plasma column. Imposing $d\phi_m = 0$, the change in the corresponding internal magnetic pressure becomes $dp_{\text{int}} = -(2B_z^2/\mu_0 r) dr$.

The variation in the external magnetic pressure, i.e., the pressure associated to the magnetic field produced by the plasma current, is readily obtained, $dp_{\text{ext}} = -(B_a^2/\mu_0 r) dr$. For stability, it is necessary that $dp_{\text{int}} > dp_{\text{ext}}$, or

$$B_z^2 > \frac{B_a^2}{2} \Rightarrow \beta \equiv \frac{p_0}{B_z^2/2\mu_0} < 2 \quad (3)$$

In this last expression, we have used the equilibrium condition and introduced the parameter β , which is the ratio between plasma and magnetic pressures. This parameter appears in the stability condition of almost all macroscopic instabilities in magnetically confined plasmas and, for actual configurations, it is usually limited to values much below unity. The current flowing in the plasma column can also drive another type of instability called a kink instability, which is associated with helical perturbations of the plasma column. These perturbations require a more sophisticated model to be properly described and, in its simplest version, the stability condition is given by (see Chapter 6 of Myamoto, 2016).

$$\left| \frac{B_a}{B_z} \right| < \frac{2\pi a}{L} \quad (4)$$

where L is the length of the plasma column. This condition is called the Kruskal-Shafranov criterion, after M.D. Kruskal and V.D. Shafranov, who independently derived it in 1958. We see that, in this simple model, the stability condition is not directly associated with the value of β , but with the pitch of the magnetic field lines. In toroidal configurations, L represents the periodic length of the plasma column, i.e., $L = 2\pi R_0$, where R_0 corresponds to an equivalent plasma major radius, and the above criterion is written in terms of the edge safety factor, q_a , where

$$q_a = \frac{aB_z}{R_0 B_a} > 1 \quad (5)$$

For a given longitudinal stabilizing field B_z , this criterion imposes a maximum plasma current I_p that can be stably driven in the plasma column.

To avoid this type of current-driven instability, it is possible to conceive magnetic configurations in which the required confining field is entirely produced by currents flowing in external coils. In fact, this is the basis of the stellarator concept, which will be discussed in “Stellarators” section. Since in a confined plasma the pressure usually decreases outwards, one basic question is whether pressure perturbations can be unstable in this case. The instabilities that are most prone to be excited are those that distort the least the magnetic field lines, avoiding the back reaction due to magnetic tension along field lines. One such instability is the so-called interchange mode, where an adiabatic radial exchange of flux tubes occurs. A flux tube is a tube formed by field lines, i.e., a tube with a constant magnetic flux through its cross section dS , so that its volume is given by $V = \int d\mathcal{L} dS = d\phi \int d\mathcal{L}/B$, where $d\psi = BdS$, is the magnetic flux and the integral is carried out along the entire field line. Let us then suppose that a perturbation interchanges radially two flux tubes of equal flux but with pressures and volumes (p_I, V_I) and (p_{II}, V_{II}) . Because the plasma is a highly conductive fluid, it is “frozen” to the magnetic field lines and moves along with the flux tubes. Since these have equal flux, the magnetic energy remains unchanged in the process. Then, only the plasma energy $W_p = pV/(\gamma - 1)$, where γ is the adiabatic index, can change; a perturbation is unstable if $\delta W_p < 0$, because, in this case, the system evolves to a lower energy state. In adiabatic processes, $pV^\gamma = \text{const}$ and the new pressure in volume V_{II} will be $p_{II} = p_I V_I^\gamma / V_{II}^\gamma$ and in volume V_I it will be $p_I = p_{II} V_{II}^\gamma / V_I^\gamma$. Assuming an incremental variation, i.e., $V_I = V$, $V_{II} = V + \delta V$, $p_I = p$, $p_{II} = p + \delta p$, it is straightforward to show that

Fig. 1 Sketch of boundary perturbation on a cylindrical plasma column permeated by a constant and uniform magnetic field.

$$\delta W_p = \delta p \delta V + \gamma p \frac{\delta V^2}{V} \quad (6)$$

Since the second term on the right-hand side is always positive, it turns out that a sufficient condition for stability is $\delta p \delta V > 0$. Since in confined plasmas $\delta p < 0$, this condition implies that $\delta V = d\phi \delta(\int d\mathcal{L}/B) < 0$, that is, the magnitude of the magnetic field inside the flux tube has to increase. Magnetic configurations that satisfy this condition have field lines that are convex with respect to the region where the plasma is confined and are called magnetic wells. In closed magnetic configurations, a magnetic well can be achieved only in an average sense, as will be discussed later. Macroscopic instabilities, either pressure gradient- or current-driven, are usually referred to as MHD instabilities, because they can be well described by a magnetohydrodynamic model of the plasma (Goedbloed and Poedts, 2004).

The particle and energy transport in magnetically confined plasma is a process that still cannot be accurately described from first-principle models. Considering the standard random-walk collisional transport model, the classical diffusion coefficient should be $D = \rho_\alpha^2 / \tau_\alpha$, where τ_α is the characteristic collision time of particle species α . This result comes from the assumption that, after a collision, the characteristic step size across the magnetic field is of the order of ρ_α . This classical diffusion coefficient can be written in terms of practical units used in fusion research as

$$D = 2.0 \times 10^{-3} \frac{n}{B^2 \sqrt{T}} \left(\frac{\text{m}^2}{\text{s}} \right) \quad (7)$$

where B is the magnetic field, expressed in Tesla, n is the plasma density, expressed in units of 10^{20}m^{-3} , and T is the plasma temperature, expressed in keV. This is a quite optimistic result, as it indicates that the energy confinement should increase with the square of the magnetic field strength and with the square root of the plasma temperature. Considering typical parameters of current large fusion devices ($T = 10 \text{ keV}$, $n = 0.5 \times 10^{20} \text{m}^{-3}$ and $B = 3 \text{ T}$), one obtains $D = 3 \times 10^{-5} \text{m}^2/\text{s}$. Typical experimental values are not only five orders of magnitude larger than this, i.e., $D \approx 1 \text{m}^2/\text{s}$, but they also show a much less favorable scaling, following variations of the so-called Bohm empirical diffusion coefficient, $D_B \approx k_B T / 16eB$ (MKS units). The ratio between the two diffusion coefficients is $D_B/D \approx \omega_{ce} \tau / 16$, so that the experimental results approach the values predicted by the Bohm diffusion coefficient as the magnetic field and plasma temperature increase, making the plasma less collisional. The main reasons for this observed anomalous diffusion have been attributed to plasma micro-scale turbulence and the convective transport associated with it. Thus, in the comparison of different confinement schemes, it is important to take into consideration the level of anomalous transport. This is usually gauged by estimating their energy confinement time, defined as

$$\tau_E = \frac{\frac{3}{2} n k_B T}{P_{in}} \quad (8)$$

where P_{in} is the input power necessary to balance energy transport and radiation, and, therefore, to maintain the plasma at temperature T .

In what follows, the performance of different magnetic confinement schemes will be expressed not only in terms of the maximum values of their temperature and density, but also by the values of the parameters β , I_p , and τ_E , when applicable.

Linear devices

The basic advantage of linear devices is their geometric simplicity, making it somewhat easier, from an engineering perspective, the design of the components required for fusion reactors, such as magnetic coil systems, plasma control and heating systems, neutron blanket, etc. However, the simplest magnetic configuration one could envisage, a straight cylinder, such as that produced by a very long solenoid, would not work because the charged particles would leave by streaming out of its ends. A basic scheme to overcome these end losses is to increase the magnitude of the field at the ends of the cylinder, so that the charged particles feel a reflective force as they approach them. This effect occurs because the circular motion of a charged particle in a magnetic field produces a magnetic moment that opposes the external field. So, the particle movement towards the ends of such a straight configuration, with increasing field strength, can be seen as the effect of two magnets of identical poles facing each other.

Magnetic mirror

The first magnetic mirror systems were independently proposed in the middle 1950s by G.I. Budker, in the Soviet Union, and R.F. Post, in the United States (Beklemishev et al., 2012). The basic magnetic configuration is simply that produced by two coaxial coils, separated by some distance, as shown in Fig. 2A. Neglecting collisions, two main constants of motion are adiabatically conserved as the charged particles move between the two mirror throats, spiraling around the magnetic field lines, the particle's total energy, $E = mv^2/2$, and magnetic moment, $\mu_m = mv_\perp^2/2B$ (see Chapter 3 of Bittencourt, 2004). Denoting the values of the physical constants at the center of the mirror by the index "0", i.e., v_0 , $v_{0\perp}$ and B_0 , and the maximum value of the magnetic field at the mirror throat by B_m , it follows from the conservation of the adiabatic constants of motion that the condition

$$\sin(\theta) = \frac{v_{0\perp}}{v_0} > \sqrt{\frac{B_0}{B_m}} \quad (9)$$

Fig. 2 (A) Basic magnetic mirror configuration and (B) loss-cone in space velocity. (A) Reproduced from Fig. 1 of Beklemishev AD, et al. (2012) *Magnetic mirrors: History, results, and future prospects. Problems of Atomic Science and Technology* 6: 8–12. <https://vant.kipt.kharkov.ua/TABFRAME2.html>, and (B) reproduced from Fig. 2.5 of Myamoto K (2016) *Plasma Physics for Controlled Fusion*. Springer.

must be satisfied for particles to be confined. This angle establishes a loss-cone in velocity space, as pictured in Fig. 2B. Particles that enter the loss-cone are lost, and, as a consequence, the particle distribution function in a mirror device is non-Maxwellian. Since Coulomb collisions between particles of the same species lead to chaotic diffusion in velocity space, trapped ions eventually fall in the loss-cone, so that the basic particle confinement time, τ_p , in mirror devices is proportional to the ion-ion collision time (Sivukhin, 1966), τ_{ii} ,

$$\tau_p = \tau_{ii} \ln \left| \frac{B_m}{B_0} \right| \quad (10)$$

For a deuterium plasma with $T = 10 \text{ keV}$ and $n = 1 \times 10^{20} \text{ m}^{-3}$, one obtains $n\tau_p = 8 \times 10^{17} \ln |B_m/B_0| \text{ m}^{-3} \cdot \text{s}$, i.e., a value well below that required for a fusion reactor (see Chapter 12.02). The non-Maxwellian distribution function also provides a source of free energy to drive velocity-space instabilities (Guest and Dory, 1965), whose non-linear evolution increases substantially the anomalous energy transport from the plasma.

It was theoretically predicted by Rosenbluth and Longmire that a symmetric mirror configuration should be MHD unstable, at all values of β (Rosenbluth and Longmire, 1957), to the flux tube interchange instability described in “Magnetic confinement basics” section. Although this instability was not seen in the first mirror experiments, it was identified by M.S. Ioffe in the PR-2 device, in 1961. He subsequently proposed a technique for avoiding this instability by adding a quadrupole magnetic field to the symmetric mirror field (Gott et al., 1962). The combination of the two fields produces a magnetic well configuration, in which $|B|$ increases in all directions. Other “minimum-B” configurations, in particular the “baseball-shaped coils,” were later proposed, and MHD stable plasmas were confined in mirror devices with $\beta > 1$ (Turner et al., 1979).

Despite the good MHD results, the single mirror minimum-B plasma column is highly asymmetric, and the experiments carried out in different devices have show rather poor energy confinement, that is, enhanced anomalous transport. These results, and the need to reduce end losses, lead to the development of the “tandem-mirror” concept, which became the main line of mirror research. The configuration is basically long solenoidal mirror with minimum-B cells at both ends. These not only play the role of “MHD anchors,” but also provide a localized volume where highly energetic neutral particles can be injected and the electrons strongly RF-heated. With this scheme, the ambipolar field in these “end-plugs” can be properly shaped to minimize particle losses (Beklemishev et al., 2012). However, the transition from the axisymmetric field of the central cell to the quadrupole anchors requires the addition of extra quadrupole fields, which increase the local asymmetry, spoiling the MHD stability and energy confinement of the device. The basic scheme of a tandem-mirror configuration is sketched in Fig. 3A (Fowler et al., 2016). A drawing of GAMMA-10, the world largest tandem mirror device, is shown in Fig. 3B (Imai et al., 2011). It has a more sophisticated design, including an axisymmetric mirror cell after each MHD anchor. The central coil length is $L = 5.6 \text{ m}$, with central magnetic field $B_0 = 0.4 \text{ T}$ and mirror ratio $B_m/B_0 = 5.2$. The plug/barrier cell has a length $L = 2.5 \text{ m}$, with magnetic-field at the midplane $B_0 = 0.5 \text{ T}$, and mirror ratio $B_m/B_0 = 6.2$.

In GAMMA-10, the ions are heated by ion-cyclotron resonance heating, ICRH, and the electrons by electron cyclotron resonance heating, ECRH. It has reached large ion temperatures ($T_i \approx 10 \text{ keV}$) and good values for the ambipolar plugging potential ($V \approx 500 \text{ V}$), reducing end-losses by a factor of 100. However, some other parameters remained modest: $T_e, \text{max} \approx 300 \text{ eV}$, $n_{\text{max}} = 1 \times 10^{19} \text{ m}^{-3}$, $\beta \approx 0.05$ and $\tau_E \approx 10 \text{ ms}$. Recently, the main scientific objective of GAMMA-10 was changed to divertor studies under similar condition of actual fusion devices. With additional RF wave heating, the ion flux at the end-mirror exit was increased to $3.3 \times 10^{23} \text{ m}^{-2}$, delivering a maximum heat flux of 21 MW/m^2 , which is of the order of that expect on the divertor plates of ITER (Nakashima et al., 2016).

An alternative scheme to the tandem mirror, keeping the attractive geometry of axisymmetric mirrors, was proposed in 1979 at the Budker Institute of Nuclear Physics (Mirnov and Ryutov, 1988). The fundamental rationale of the proposal was to have a central cell long enough, and with sufficiently high plasma pressure, to make the ion-ion mean-free-path smaller than the length L of the cell. In this case, there is enough time for collisional velocity-space isotropization, before the ions in the loss-cone escape the confinement region. The distribution function becomes isotropic and Maxwellian and the particles escape with velocities of the order of the ion-acoustic speed, $v_s = \sqrt{\gamma k_B T / m_i}$, where γ is the ratio of specific heats and m_i the effective ion mass. The

Fig. 3 (A) Sketch of a tandem-mirror magnetic confinement configuration and (B) drawing of the GAMMA-10 tandem mirror. The electrons inside the end-plugs are strongly heated by electron cyclotron waves (ECH) and the ions are fueled and heated by neutral-beam injection (NBI). The resulting ambipolar potential acts to decrease particle end loss. (A) Reproduced from Fig. 1 of Fowler TK, Moir RW and Simonen TC (2016) Prospects for an axisymmetric advanced fuel tandem mirror. *AIP Conference Proceedings* 1771(1): 080003. <https://aip.scitation.org/doi/abs/10.1063/1.4964242>, and (B) reproduced from Fig. 1 of Nakashima Y, Imai T, Sakamoto M, Katanuma I, Kariya T, Yoshikawa M, Ezumi N, Minami R, Hirata M, Kohagura J, Numakura T, Ikezoe R, Ichimura K, Wang X and Ichimura M (2016) Overview of recent progress and future in GAMMA 10/PDX project. *AIP Conference Proceedings* 1771(1): 020002. <https://aip.scitation.org/doi/abs/10.1063/1.4964155>.

resulting particle confinement time becomes $\tau_p = (B_m/B_0)L/v_s$, and, because of the dependence on the ratio between length and thermal speed, this configuration was dubbed Gas Dynamic Trap (GDT). Quite good results were obtained in the GDT experiments at the Budker Institute, with high mirror ratio, $B_m/B_0 = 35$; plasma density $n \approx 7 \times 10^{18} \text{m}^{-3}$, electron temperature $T_e \approx 650 \text{eV}$, energy confinement time $\tau_E \approx 0.5 \text{ ms}$, and $\beta \approx 0.6$ (Bagryansky et al., 2015).

Although a fusion reactor based upon the GDT concept would have to be quite long, $L \approx 1 \text{ km}$, it was recognized that a much shorter device, with modest electron temperature, $T_e \approx 1 \text{ keV}$, would be suitable for a deuterium-tritium neutron source, a facility needed for material testing in the fusion program (Ivanov and Prikhodko, 2013). This stimulated further investigation of this scheme, evolving to the concept of the gas-dynamic multiple-mirror trap (Postupaev et al., 2016). The GOL-NB multiple mirror was then built in the Budker Institute of Nuclear Physics and the results of the testing of its baseline systems were recently reported (Postupaev et al., 2019). The plasma is heated in a central cell of length $L = 2.5 \text{ m}$ by neutral beams of 0.75 MW of power at 25 kV injection energy. The plasma filling gun was successfully tested, providing plasmas that lasted for 2 s with $n \approx 8 \times 10^{19} \text{m}^{-3}$. The results in GDT and GOL-NB have inspired new possibilities for a mirror fusion facility, not only as a neutron source, but also as an advanced fuel reactor (Fowler et al., 2016).

Toroidal devices

The most straightforward closed magnetic confinement configuration is a toroidal solenoid, as sketched in Fig. 4A. The stabilizing magnetic field is produced by external coils placed around a toroidal chamber. Assuming that the number N of coils is large enough and that they are closely packed, so that their discreteness can be neglected in first approximation, the magnetic field can be easily calculated from Ampere's law,

$$B = \frac{\mu_0 N I}{2\pi R} \hat{e}_\phi \quad (11)$$

Fig. 4 (A) Magnetized toroidal plasma column and (B) particle drift orbits.

where N is the number of coils around the toroidal chamber, I is the current in each coil, R is the radial distance from the vertical axis, and $\hat{e}_\phi$ is the unit vector in the toroidal direction. The field lines are concentric circles centered at the vertical axis.

Unfortunately, the curvature of the field lines and the gradient of the magnetic field, which increase towards the vertical axis, introduce drift effects on the orbits of the particles that limit their confinement in this simple configuration. The two effects can be modeled as constant forces along the guiding center trajectory. Incorporating these into the expression for the drift velocity, it turns out that the ions and electrons drift in opposite directions, as sketched in Fig. 4B. This charge separation gives rise to an ambipolar electric field in the vertical direction. The drift due to this field crossed with the magnetic field causes both types of particles to displace outwards, and leave the confinement region.

This problem was independently identified by Enrico Fermi and Lev Artsimovich, and two rather clever schemes were conceived to overcome it. Both relied on adding a poloidal field, to transform the simple circular toroidal field lines into helical lines winding around a toroidal axis, as shown in Fig. 5A. After completing many toroidal transits, a helical line fully covers a surface, which is therefore called a magnetic or flux surface. Consider, for simplicity, the two magnetic surfaces A and B shown in Fig. 5B and that a charge departs from position 1, at the magnetic surface A, moving along a field line. Due to the curvature and ∇B drifts, its guiding center will displace upwards, towards the magnetic surface B. It eventually reaches the inside of the toroidal magnetic surface at position 2. As its guiding center goes on moving along the magnetic field, it keeps drifting upwards, so that it returns to the magnetic surface A at position 3, which corresponds to position 1 displaced toroidally, as indicated in Fig. 5A. Therefore, the displacements from the original magnetic surface A are somewhat compensated in one pitch of the helical field line.

It turns out, however, that due to the collective behavior of particle populations, as expressed by the pressure and current, plasma confinement is not entirely prescribed by the orbits of individual particles. The equilibrium in a magnetic configuration has to locally satisfy the pressure balance equation, already presented, $\nabla p = \mathbf{J} \times \mathbf{B}$, where $\mathbf{J}$ and $\mathbf{B}$ are, respectively, the self-consistent current density and magnetic field in the plasma, which are related through Ampère's law $\nabla \times \mathbf{B} = \mu_0 \mathbf{J}$. It follows from the equilibrium equation that $\mathbf{B} \cdot \nabla p = 0$, so that the constant-pressure surfaces have to coincide with the magnetic surfaces, in which the magnetic field lines lie. Therefore, to maintain a confined plasma, the magnetic surfaces must be closed and nested, enclosing a central field line called the magnetic axis.

In three-dimensional geometry, the existence of nested magnetic surfaces requires some underlying continuous spatial symmetry (Grad and Rubin, 1958; Grad, 1967). This is the case of magnetic configurations that preserve axisymmetry, i.e., that are independent of the toroidal angle ϕ . To see this, consider the combination of two simple magnetic field configurations presented in standard textbooks. The first, Fig. 6A, is the field produced by a vertical straight current I_1 . The resulting field $\mathbf{B}_1$ is in the toroidal direction $\hat{e}_\phi$ and the magnetic field lines are just closed circles centered at the vertical axis. The second configuration is the field produced by

a circular current loop I_2 . The field calculation, in this case, although somewhat more involved, is outlined in advanced textbooks. The expression for the field is given in terms of elliptic integrals, and the field B_2 lies on vertical planes perpendicular to the current loop, and these are denoted poloidal planes. The field lines are circles displaced outwards with respect to the current loop, as sketched in Fig. 6B. Considering the two currents in conjunction, the resultant magnetic field, $B_1 + B_2$, will then form helical field lines on toroidal surfaces, as sketched in Fig. 6C. This system with two current sources has axisymmetry and the flux surfaces are nested, as indicated by the surfaces with labels ψ_1 , ψ_2 and ψ_3 in Fig. 6C (Fasoli et al., 2016).

This scheme to create nested magnetic surfaces is the basis of the tokamak concept. It obviously requires a toroidal current flowing inside the plasma column (modeled by current I_2 in the example). However, it is possible to create nested magnetic surfaces using only currents flowing in coils outside the plasma column, and this is the stellarator concept. Both the tokamak and the stellarator configurations will be discussed in detail in the next subsections. One important parameter of the magnetic surfaces is the degree of “twistiness,” or helicity, of the field lines embedded within it. This is quantified by a parameter called rotational transform ι , defined so that the average angular advance of a field line, each time it crosses the same poloidal cross-section of the magnetic surface, after one toroidal turn, is given by $\Delta\theta \approx 2\pi\iota$. Considering that, in general, the field lines transit ergodically over the magnetic surfaces, a more exact definition of the rotational transform is (Morozov and Soloviev, 1966).

$$\iota = \lim_{m \rightarrow \infty} \frac{\sum_{k=1}^m (\Delta\theta)_k}{2\pi m} \quad (12)$$

where $(\Delta\theta)_k$ is the poloidal angular displacement of a field line after its k th toroidal transit. On rational magnetic surfaces, it turns out that $\iota = n/m$, i.e., the field lines close on themselves after m toroidal and n poloidal transits, where m and n are integers.

Tokamaks

The tokamak magnetic configuration was originally conceptualized by two Nobel laureate soviet physicists, Igor Tamm and Andrei Sakharov, in the beginning of the 1950s (Kadomtsev, 1988). The T-1 device, Fig. 7A, is considered to be the first tokamak to operate. It was developed under the leadership of the Ukrainian physicist Natan Yavlinsky, at the Kurchatov Institute, Moscow (Smirnov, 2009; Azizov, 2012). Although its electron temperature was rather low, due to strong line radiation from impurity ions present in the plasma, it has, for the first time, given experimental evidence of stable plasma confinement satisfying the Kruskal-Shafranov condition.

The program on development of tokamaks progressed firmly and successfully in the Kurchatov Institute during the 1960s under the leadership of L. Artsimovich, progressing not only experimentally, but also establishing the theoretical physics basis of plasma confinement in these devices. This continuous effort led to the outstanding results obtained in the T-3 tokamak, Fig. 7B, reported by Artsimovich in the Third International Fusion Conference held in Novosibirsk, Soviet Union, in 1968 (Artsimovich et al., 1968). Plasma discharges stable to kink modes with $q_a \geq 6$ were produced with plasma density $n \approx 3 \times 10^{19} \text{ m}^{-3}$, electron temperature $T_e \approx 1 \text{ keV}$, ion temperature $T_i \approx 350 \text{ eV}$, and energy confinement time $\tau_E \approx 3 \text{ ms}$, i.e., about 10 times better than that predicted by the Bohm anomalous diffusion coefficient. These plasma discharges exhibited the first evidence of thermonuclear neutron production in a confined plasma. However, these results, which were much better than those obtained in any other fusion device then under investigation, were received with some skepticism by scientists from other national laboratories. The main reason for the doubts was that the plasma temperature in T-3 was indirectly estimated through the diamagnetic effect of the plasma, that is, the decrease of the magnetic field as its pressure increases (see Chapter 2 of Hutchinson, 2005), and this method is known to be

Fig. 7 (A) The T-1 and (B) T-3 tokamaks in the Kurchatov Institute, Moscow. The former started operating approximately in 1958 and the latter in 1962. inaccurate if runaway electrons (non-thermal highly energetic electrons) are present in the plasma. Artsimovich then invited Bas Pease, head of the Culham Laboratory, United Kingdom, to send a team of specialists to Kurchatov, to measure the electron temperature in T-3 using a new diagnostic system they had developed, based on the Thomson scattering effect (see Chapter 7 of [Hutchinson, 2005](#)). The invitation was accepted and the measurements fully confirmed the results reported by Artsimovich ([Peacock et al., 1969](#)). Since the first devices, around 200 tokamaks have been built in the World ([Wordpress, n.d.](#)).

The main features of a tokamak can be seen in [Fig. 8](#). The toroidal magnetic field is produced by external coils, TFC, outside the vacuum chamber. It is relevant to point out that, instead of circular coils, modern tokamaks use D-shaped coils, as shown in the figure. Due to the $1/R$ dependence of the toroidal field, this shape keeps the coil in a pure tension state, minimizing the bending moment in its plane. The poloidal field is mainly produced by the current flowing in the plasma, I_p , and by external poloidal field coils, PFC. These coils produce a vertical field, to balance the hoop expansion force of the plasma column, and radial fields to shape its cross section and feedback control its vertical position. The flux surfaces are nested around a planar magnetic axis, whose radius is denoted by R_0 , and the half-width of the outer most surface, which is the plasma boundary, is denoted by a . The ratio between these two quantities is called the aspect ratio, $A = R_0/a$. The current is induced in the plasma by varying the magnetic flux in the central solenoid, CS. Therefore, the plasma column plays the role of a one-loop secondary coil of a transform whose primary coil is the central solenoid. In the conventional tokamak design, this so-called Ohmic heating transformer (because I_p Ohmically heats the plasma) has an iron yoke. However, modern tokamaks use only an air-core CS, in series with extra PFCs to minimize stray fields in the plasma volume. This allows the design of tokamaks with small A , which improves the MHD stability of the plasma and reduces the current in the TFCs ([Peng and Strickler, 1986](#)). The necessity of inducing the plasma current is the main drawback of the tokamak concept because it makes it intrinsically a non-steady-state device. However, techniques to overcome this difficulty, at least partially, have been developed, in particular, current drive by electromagnetic waves ([Fisch, 1987](#)).

Due to axisymmetry in tokamaks, the MHD equilibrium equation, $\nabla p = \mathbf{J} \times \mathbf{B}$, can be transformed into a second-order, non-linear, elliptic partial differential equation for the flux function, $\psi = RA_\phi$, where A_ϕ is the toroidal component of the vector potential,

$$\frac{\partial^2 \psi}{\partial R^2} - \frac{1}{R} \frac{\partial \psi}{\partial R} + \frac{\partial^2 \psi}{\partial Z^2} = -\mu_0 R \left[R \frac{dp}{d\psi} + \frac{F}{\mu_0 R} \frac{dF}{d\psi} \right]. \quad (13)$$

This equation was independently obtained by Harold Grad and Vitaly Shafranov and, therefore, is named the Grad-Shafranov (GS) equation ([Mukhovatov and Shafranov, 1971](#)). The solution to this equation provides a 2-D map of the magnetic flux surfaces, such as that shown in [Fig. 9](#). It must be solved with either Dirichlet or Neumann boundary conditions specified along the boundary of a closed domain and, in some rather simple cases, this can be carried out analytically. However, in practical cases it is solved numerically, using robust schemes that have been developed over the years ([Jardin, 2010](#)). The source terms of the GS equation are two free functions: plasma pressure, $p(\psi)$, and poloidal current function, $F(\psi)$. While the pressure profile can be reasonably well specified, based on experimental data or transport modeling, specifying F is not straightforward. This difficulty arises from F often being nearly constant across the plasma and, therefore, $dF/d\psi$ is entirely dependent on small deviations of F away from constancy.

In axisymmetric confinement configurations, it is usual to specify the helicity of the magnetic field lines in each magnetic flux surface by the inverse of the rotational transform, through the parameter $q = 1/i$. This parameter is called the safety factor because its profile across the plasma plays a fundamental role on MHD stability. Rational surfaces correspond to $q = m/n$ and instabilities with this helicity can develop in their neighborhood, where the restoring force associated with the plasma displacement is reduced ([Goedbloed and Poedts, 2004](#)).

The plasma is confined within the flux surfaces and the last closed flux surface (LCFS) defines the shape of the plasma cross-section. The region outside the LCFS, denoted the scrape-off layer (SOL), is normally filled with a partially ionized

low-temperature plasma. The closed flux surfaces are not concentric with the magnetic axis because, due to toroidicity and pressure gradient, they displace outwards; the largest displacement being that of the magnetic axis with respect to the geometric center of the LCFS. This is called the Shafranov shift and is proportional to the plasma β (Mukhovatov and Shafranov, 1971). In the first tokamaks, the plasma cross-section was circular, and the last closed flux surface was established by contact of the plasma column with a material limiter, normally a carbon block. Later, it was realized that the stability of tokamaks to MHD modes is substantially improved if the plasma cross section is elongated in the vertical direction, assuming a D-shape (Freidberg, 1982).

In high-temperature and high-density plasmas, a large amount of power in energetic particles and radiation is transported across the magnetic surfaces and impinges upon the plasma-facing parts of the tokamak vacuum chamber. When material limiters are employed, this causes large erosion and the generation of impurities with a range of atomic numbers, depending on the material composition of the limiter and vacuum vessel walls. These impurities drift back into the plasma leading to increased line radiation, diluting the fuel and spoiling the fusion performance. To separate this source of impurities from the main plasma, a concept called magnetic divertor was suggested by Spitzer (1958). It is based on the introduction of a stagnation X-point in a flux surface external to the plasma column, so that the field lines become open in the SOL. This surface is dubbed the separatrix. The value of the safety factor diverges as one approaches the separatrix because, at the X-point, $\nabla\psi = 0$ and the magnetic field becomes purely toroidal, causing the rotational transform to vanish and the safety factor to diverge. Because of this, for gauging the stability of diverted tokamaks to kink modes, it has been established to replace the value of the safety factor at the LCFS by $q_{95} = q(\psi_N = 0.95)$ where ψ_N is the normalized flux function ($\psi_N = 0$ at the magnetic axis and $\psi_N = 1$ at the separatrix). In the SOL beyond the separatrix, energetic particles and heat are directed to divertor plates that can be designed to handle high heat loads and sputtering, the divertor plates.

After 1970, more advanced tokamaks were designed with non-circular plasma cross-section and a magnetic divertor. As an example, the largest tokamak in operation, the Joint European Torus (JET) (Euro-Fusion, n.d.), was initially designed with non-circular cross-section only and later modified to introduce a magnetic divertor. The change in the flux surfaces due to this modification can be seen in Fig. 9 (Wischmeier, 2016). Despite the reduction in plasma size and maximum plasma current, its performance with the magnetic divertor increased substantially, in particular regarding energy confinement. The introduction of a magnetic divertor not only allowed cleaner discharges, but led to a much better understanding of the relevance of edge-plasma phenomena for the performance of tokamak plasmas and also to the experimental discovery of an improved mode of operation - the high confinement mode (H-mode) (Wagner et al., 1982), in which the energy confinement time doubles with respect to that in the standard so-called low-confinement mode (L-mode). Although the transition from L- to H-mode still defies a self-consistent theoretical explanation, the H-mode has been reproduced in all major magnetic confinement devices, including stellarators and tokamaks, and with other plasma heating methods, such as RF heating (Gong et al., 2019).

Plasmas operated in the H-mode feature a steep pressure profile in the edge region, usually called the pedestal region, which leads to increased plasma density and temperature in the plasma core region. Therefore, the H-mode is characterized by an External Transport Barrier (ETB) close to the plasma edge. Besides the H-mode, other improved confinement regimes have also been observed, such as the Internal Transport Barrier (ITB). This typically occurs when the q -profile does not increase monotonically from the magnetic axis to the plasma boundary, presenting a minimum in an intermediate flux surface. This is called a

reverse-shear configuration, because the differential twist of the field lines change direction at this surface. For comparison, the plasma temperature profile in the different confinement regimes is illustrated in Fig. 10 (Zohm, 2015). Because the ITB is produced only transiently, the H-mode is seen as the most promising operational regime for an economically attractive fusion power plant. However, the H-mode is not a quiescent plasma regime due to the ubiquitous presence of repetitive instabilities known as edge localized modes (ELMs), which are driven by MHD instabilities termed peeling-ballooning (P-B) modes, triggered by the increased plasma pressure gradient and/or parallel current density in the plasma edge (Snyder et al., 2002).

A major achievement of tokamaks, not yet matched by any other magnetic confinement scheme, was the production of significant amounts of fusion power by the Tokamak Fusion Test Reactor (TFTR) and JET, operating with deuterium-tritium fueled plasmas. These two important tokamaks are shown in Fig. 11. While TFTR produced about 10.7 MW of fusion power (Bell, 2016a), JET retains the world record of peak fusion power produced, which is 16.1 MW. The promising results obtained in the last three decades in tokamaks led to the proposal of a prototype reactor, the ITER, that is being built in Saint-Paul-lès-Durance, France, by a consortium of countries, China, the European Union (including Switzerland), India, Japan, Russia, South Korea, and the United States. ITER will become the largest tokamak in the world and, among other goals, it was designed to operate in the H-mode, with $I_p = 15$ MA and $q_{95} = 3$, and to produce about 500 MW of fusion power, which will correspond to a D-T fusion power gain $Q_{DT} \geq 10$.

Conventional tokamaks usually have aspect ratio $A = R_0/a \approx 3 - 4$. However, during the 1980s, it was conjectured by two researchers from the Oak Ridge National Laboratory (ORNL), Ben Carreras and Tim Hender, that tokamaks of low-A, also termed spherical tokamaks (STs), could be more stable against MHD instabilities and should have a number of substantial practical

advantages over conventional aspect ratio devices (Peng and Strickler, 1986). In STs, the poloidal field in the outboard region is comparable with and larger than the toroidal field, while the fields in the inboard region are comparable. In addition, the toroidal circumference of the plasma in the outboard region is comparable with the poloidal circumference, but it is substantially shorter than the poloidal circumference in the inboard region. As shown in Fig. 12A, these two effects lead to highly pitched field lines in the outboard region and moderately pitched field lines in the inboard region, in comparison with those in conventional aspect ratio plasmas. As a consequence, most of the field line length is located in the inboard region, also called good magnetic field curvature region (good in terms of MHD stability), while only a small fraction of it is located in the outboard, also called bad magnetic field curvature. Theoretical studies indeed showed that not only the classic kink instability should be strongly suppressed by this improved average magnetic field curvature, but also ballooning modes, which are radially localized instabilities that develop predominantly perpendicular to the confining magnetic field, but whose perturbation has a finite parallel component, and that is driven by the plasma pressure gradient in regions of unfavorable magnetic field curvature. Due to its higher average pitched angles, and therefore higher values of safety factor, STs allow stable operation at higher plasma current and β . These properties, among others, suggested that low-A machines would not only be less expensive to build, but have better performance as well. The first ST to be built was the Small Tight Aspect Ratio Tokamak (START). It featured a minimum aspect ratio $A = 1.2$ and major radius $R_0 = 32.5$ cm. It was constructed at the Culham Centre for Fusion Energy and started to operate in January 1991. In its earliest operations, START plasmas showed improved plasma stability, as predicted by Peng and Strickler, and the maximum β -values, achieved with ohmic heating alone, were as high as those obtained on the DIII-D tokamak with NBI (~ 0.12) (Strait, 1994; Sykes, 1997). When neutral beam heating was added, the maximum values of β were about three times higher than those obtained in any conventional tokamak (Akers et al., 2002). In view of its improved performance and lower cost, with respect to conventional aspect ratio tokamaks, STs have attracted considerable interest within the fusion scientific community and a number of STs since been constructed, including MAST, NSTX, Pegasus, Globus-M, among others (see Fig. 12B for an image of a plasma in the MAST tokamak). However, despite the improvements in performance observed in STs, their development has been one generation behind that of conventional aspect ratio machines and their tightness makes it difficult to properly shield their central column against radiation damage in a fusion reactor. However, with the advent of high temperature superconductors, new technological routes have appeared and STs, as well as compact, high-field tokamaks, are again attracting great attention (Whyte, 2019).

Stellarators

In the stellarator concept, the helical magnetic field is entirely produced by coils placed external to the plasma column. Therefore, one of its advantages, with respect to tokamaks, is that it does not require a current to be induced in the plasma, so that it is intrinsically steady state. One scheme to accomplish this was originally proposed by Lyman Spitzer, in a meeting at the American Atomic Energy Commission in 1951. The basic idea was that the helicity of the field lines could be achieved by twisting the torus, around which the circular coils that produce the magnetic field are placed, into a figure-eight configuration, as sketched in Fig. 13A taken from a review on fusion research by Braams and Stott (2002). This scheme, dubbed the “Figure-Eight Stellarator,” was explained by Spitzer in a seminal paper published in 1958 (Spitzer, 1958). Some devices based upon this concept were actually built at the Princeton Plasma Physics Laboratory, but their first results were somewhat disappointing.

One of the drawbacks of the Figure-Eight stellarator concept is that the twisted magnetic axis, around which the helical field lines wind, lacks the underlying symmetry required for the existence of closed and nested magnetic surfaces. Therefore, any small perturbation driven by error fields can break up the closed magnetic surfaces, creating the so-called magnetic islands and stochastic regions, similar to the effect predicted by the KAM theorem in Hamiltonian Particle Dynamics (Boozer, 2005). Later, Spitzer conceived a simpler configuration, in which a planar toroidal magnetic field is produced by circular coils, as in a standard toroidal solenoid, and the helical field lines are produced by $\mathcal{L}$ helical dipole windings wound around the toroidal vacuum chamber, with toroidal periodicity number n , as sketched in Fig. 13B for $\mathcal{L} = 2$ and $n = 5$. This turned out to become the classical stellarator

Fig. 12 (A) Schematic drawing showing a field line in the plasma edge region for two configurations: conventional aspect ratio and low aspect ratio. (B) Visible light image of a plasma discharge in the MAST spherical tokamak.

Fig. 13 (A) Sketch of the Figure-Eight stellarator and (B) the classical stellarator concept. Reproduced from Braams CM and Stott PE (2002) *Nuclear Fusion—Half a Century of Magnetic Confinement Fusion Research*. Bristol, UK: IOP Publishing.

concept, which was adopted in some later devices. The following explanation on how the nested magnetic surfaces are produced in this configuration has been extracted from the excellent introductory article on stellarators by Boozer (1998).

Let us start with the toroidal configuration shown in Fig. 6C, with closed magnetic surfaces. Most of the field lines do not close on themselves after any number of turns in the toroidal direction and continue to wind helically around the torus densely covering a magnetic surface. Those that close on themselves after an integer numbers of turns in both directions are called rational field lines. Let us consider a field line that closes on itself after one turn in the toroidal and poloidal directions, and let us now introduce a third current I_3 flowing in a helical coil coincident with it. The field produced by this current will disturb the field on the magnetic surfaces, breaking up the original field lines that approach the helical coil and splitting the magnetic surfaces to make a magnetic island, as shown in Fig. 14. The field lines inside this island form nested helical magnetic surfaces with no current inside.

The rotational transform defined in Eq. (12) plays a quite relevant role on the stability of plasmas confined in stellarators and it is a basic parameter to be specified in their design. It may appear somewhat surprising that the rotational transform of the field lines can be obtained inside a volume without currents, even close to the magnetic axis. The reader interested in looking deeper into this question is kindly directed to a review paper on stellarators by Helander (2014, 2018).

Another relevant quantity in the design of stellarators is the magnetic well, which is important for the stability of pressure-driven modes, as explained in “Magnetic confinement basics” section. In a closed magnetic configuration, topologically equivalent to a torus, it is not possible to have the plasma volume always facing convex field lines; in some regions the field lines will be convex and in others concave. The former are called good curvature regions and the latter bad curvature regions. Therefore, a magnetic well can be achieved only in an average sense, i.e., the average magnetic field strength on the flux surfaces increases with the enclosed volume, and it is defined as a dimensionless parameter on each flux surface,

$$\hat{f} = \frac{V}{\langle B^2 \rangle} \frac{d\langle B^2 \rangle}{dV} \quad (14)$$

The importance of a vacuum magnetic well depends on the profile of the rotational transform and, as the value of β increases, a magnetic well is self-generated by the plasma due to the Shafranov shift, becoming dominant over the vacuum one. Nevertheless, a vacuum magnetic well is realized in most stellarator designs.

The calculation of plasma equilibrium in three-dimensional stellarator configurations is not a trivial task. Because, in general, it is not possible to assure the existence of nested magnetic surfaces from the outset, the equilibrium MHD equations cannot be expressed in terms of an equation for a flux function ψ , as in the tokamak case. The usual procedure is then to assume their existence, at least approximately, over a large fraction of the plasma volume and to use a variational principle to minimize the total plasma energy, $W_p = \int (p/(\gamma - 1) + B^2/2\mu_0) dV$ over a toroidal domain. This is the method implemented in the widely used VMEC code (Hirshman et al., 1986).

Advanced equilibrium codes were not available at the dawn of stellarator research and several approximate methods were conceived to solve the equilibrium problem in terms of differential equations. One of the most successful schemes was developed

Fig. 14 Sketch of magnetic island with closed nested magnetic surfaces produced by the current configurations. Reproduced from Boozer AH (1998) What is a stellarator? *Physics of Plasmas*, 5(5):1647–1655. <https://doi.org/10.1063/1.872833>.

by Greene and Johnson using the so-called stellarator ordering (Greene and Johnson, 1961; Johnson and Greene, 1961). In this ordering, an assumption is made of a slender plasma column with planar magnetic axis, that is, with inverse aspect ratio $\epsilon = a/R_0 < 1$, where a and R_0 are the average minor and major radii of the plasma column. It is furthermore assumed that $\beta \sim \epsilon$ and $B_{\text{hel}}/B_{\text{tor}} \sim \sqrt{\epsilon}$, where B_{hel} is the characteristic magnitude of field generated by the helical windings and B_{tor} is the characteristic magnitude of the field produced by the toroidal solenoid. The periodic variation in the toroidal direction of the equilibrium quantities are averaged in the calculations.

Using this ordering, it is possible to qualitatively discuss one rather important issue in the MHD equilibrium of stellarators, i.e., the effect of the Pfirsch-Schlüter current (Hirsch et al., 2008). Its basic physics can be simply understood by calculating the expression for the component of the plasma current density perpendicular to the magnetic field, $J_{\perp}$. Taking the cross product $\mathbf{B} \times \nabla p$, and using the equilibrium equation, it follows that $\mathbf{J} = J_{\parallel} \mathbf{B}/B + \mathbf{J}_{\perp}$, where $\mathbf{J}_{\perp} = (\mathbf{B} \times \nabla p)/B^2$. The condition $\nabla \cdot \mathbf{J} = 0$ gives an equation for the component of the current density parallel to the field lines, $J_{\parallel}$,

$$\nabla \cdot \mathbf{J}_{\parallel} = \nabla \cdot \left(J_{\parallel} \frac{\mathbf{B}}{B} \right) = -\nabla \cdot \mathbf{J}_{\perp} = 2J_{\perp} \cdot \nabla \ln |B| \quad (15)$$

This current is called the Pfirsch-Schlüter current because they were the first to discuss its effect on stellarator equilibrium (Pfirsch and Schlüter, 1962). The Pfirsch-Schlüter current is essentially the current which flows along helical field lines to cancel the vertical separation of charges in a toroidal field. From this latter equation, it follows that the Pfirsch-Schlüter current is determined by the variation of the field strength on the magnetic surfaces. Doing the calculation in the stellarator ordering, one obtains $J_{\parallel}/J_{\perp} \approx 2 \cos(\theta)/\iota$ where $\iota = 1/q$ and θ is the poloidal angle (Miyamoto, 1978). The dipole structure of $J_{\parallel}$ gives rise to a vertical field that tends to displace the magnetic surfaces against each other. This is equivalent to the Shafranov shift Δ observed in tokamaks, but while in these devices it can be somewhat compensated by properly adjusting the equilibrium field and plasma current profile, in stellarators it can seriously affect the vacuum magnetic field configuration. Still within the stellarator ordering, and assuming that the cross-section of the plasma column is elongated by a factor $\kappa = b/a$, the expression for the shift is given by

$$\Delta = \frac{R}{\iota^2} \frac{\beta}{f(\kappa)}, \quad \text{where } f(\kappa) = \frac{\kappa + 1}{\sqrt{\kappa}} \quad (16)$$

Requiring $\Delta \leq a/2$ imposes a maximum limit on the value of β , which might be too low for a fusion reactor, if the configuration is not optimized. The Pfirsch-Schlüter current may also introduce a variation in the ι -profile, increasing its central value and decreasing its boundary value, with respect to the designed vacuum configuration. This is undesirable, because it can introduce low-order rational surfaces where localized instabilities and magnetic islands can develop, due to error fields. Therefore, optimized stellarator design aims at reducing $J_{\parallel}/J_{\perp}$ by decreasing the variation of $|B|$ on magnetic surfaces. There are four types of stellarator schemes being explored: classical stellarators (Fig. 15A), torsatrons/heliotrons (Fig. 15B) (Bell, 2016b), heliacs (Fig. 15C) (Fusionwiki, n.d.), and modular stellarators (Fig. 15D).

Classical stellarators

In the classical stellarator scheme, the helical field is produced by a set of pairs of helical coils carrying currents in opposite directions, so that they produce no net toroidal field. The toroidal field is produced by a set of toroidal field coils, as in tokamaks. The number of dipole helical coils is denoted by $\mathcal{L}$ and the number of periods by n . The magnetic field configuration of Wendelstein 7-A, W7-A, a classical stellarator with $\mathcal{L} = 2$ and $n = 5$, is sketched in Fig. 15A. Other devices with different parameters have also been constructed, such as CLEO ($\mathcal{L} = 3$ and $n = 7$), at the Culham Laboratory United Kingdom, and L - M ($\mathcal{L} = 2$ and $n = 14$), at the General Physics Institute, Moscow, Russian Federation. Usually, devices with $\mathcal{L} \leq 2$ and low value of n have an almost uniform ι -profile, meaning that the shear of the field lines between the magnetic surfaces is small. However, configurations with high shear have also attracted interest, do to its effect on the stabilization of drift instabilities, which are driven by density and temperature gradients. That is the case of L-2 M. W7-A was the largest built classical stellarator ($R_0 = 2$ m, $a = 0.1$ m, $B_0 \leq 3.4$ T) and has produced quite outstanding results. Indeed, before W7-A, practically all stellarators operated with a small plasma current, to reproduce somewhat the better performance of tokamaks. The first demonstration of classical stellarator operation without a net toroidal current was demonstrated in W7-A for the first time (Grieger et al., 1985, 1986).

Torsatrons/heliotrons

In the torsatron/heliotron scheme, the magnetic surfaces are produced by helical windings with unidirectional currents (Gourdon, 1968; Uo et al., 1971). Therefore, the magnetic field has an $\mathcal{L}$ -fold symmetry and an average vertical field is also created. Depending on the winding law, the magnitude of this field can be large, so that additional compensating vertical field coils may be required. Usually, torsatrons do not have this extra coil system whereas heliotrons do have. The scheme shown in Fig. 15B corresponds to a heliotron (LHD).

The torsatrons were more extensively investigated in the National Science Center, at Kharkov, Ukraine, in a series of devices dubbed Uragan. The last of them, Uragan-3M, has the following parameters, $R_0 = 1$ m, $a = 0.12$ m, $B_0 \leq 1$ T, $\mathcal{L} = 3$, $n = 9$, $\iota(a) = 0.3$. The experimental results of this device are still modest, with high electron temperature obtained only in small central region of the plasma column, $r \approx 3$ cm, in which a system of nested magnetic surfaces exist. Different options are currently being investigated to enlarge this region, including forcing an inward shift of the magnetic axis (Moiseenko et al., 2019).

The heliotron concept was developed in Japan and intensively investigated in the National Institute for Fusion Science, where the world largest heliotron, Large Helical Device (LHD) was put into operation in 1998, Fig. 15B. This was the first helical device with superconducting coils. Its main parameters are $R_0 = 3.5$ m, $a = 0.6$ m, $B_0 \leq 3$ T, $\mathcal{L} = 2$, $n = 10$, $\iota(a) = 0.4 \rightarrow 1.4$. The variation of the rotation transform, from the magnetic axis to the plasma boundary implies a relatively large shear of the magnetic field lines, in distinction with the low-shear option of classical stellarators. LHD has also a set of local islands divertor coils (LIDC in Fig. 15B), which allow for the production of localized magnetic divertors, for particle and energy exhaust, as in advanced tokamaks.

Particularly good results were obtained in LHD, reaching ion and electron temperatures, $T_i \approx 5.6$ keV and $T_e \approx 10$ keV, plasma density $n \approx 2 \times 10^{19} \text{ m}^{-3}$, $\beta \approx 0.05$ and energy confinement time, $\tau_E \approx 0.2$ s. In 2017, LHD started to operate with fully deuterium plasmas and the isotope dependence of the plasma performance, in particular regarding energy confinement, is being carefully investigated as a basic information for the design of fusion reactors based on this concept (Tanaka et al., 2019).

Heliacs

The heliac concept is based upon a clever arrangement of the field coils that substantially simplify their assembly and maintenance and allows additional flexibility for adjusting the value of the rotational transform ι . Circular coils are arranged helically around a central circular coil. The plasma column snakes around the latter coil, so that the magnetic axis itself has a helical structure, facilitating the production of the rotational transform (Boozer et al., 1982). The major devices built on the basis of this concept are H-1, at Canberra, Australia (Blackwell et al., 2006) and TJ-II, at CIEMAT, Madrid, Spain (Sanchez et al., 2007).

In TJ-II, Fig. 15C, there are 32 toroidal coils, two extra helical coils wound around the central conductor, and vertical field coils added for better plasma position control. The extra helical coils provide improved flexibility to control the rotational transform profile (Harris et al., 1985). The main parameters of the device are $R_0 = 1.5$ m, $a = 0.2$ m, $B_0 \leq 1$ T, $n = 4$, $\iota(a) = 0.9 \rightarrow 2.5$. In electron-cyclotron heating discharges, plasmas with $T_i \approx 100$ eV and $T_e \approx 1$ keV, and $n \approx 1 \times 10^{19} \text{ m}^{-3}$ were regularly produced. Although these parameters seem somewhat modest, many fusion relevant basic physics topics were thoroughly investigated in TJ-II, in particular, regarding sheared flows and turbulence with long-distance correlation at the plasma edge (Pedrosa et al., 2008).

Regarding the suitability for a fusion reactor, a major challenge with the heliac concept is that the highly interlinked coil system may not be acceptable, due to the necessity of introducing the blanket and radiation shielding between the plasma column and the coils.

Modular stellarators

The modular stellarator scheme was originally proposed by Wobig and Rehker (1972). The idea behind this concept was to reverse the systematic approach normally adopted in conventional stellarator design, which involved starting with the design of the coil system to achieve the desired requirements of the vacuum magnetic configuration and then determining the characteristics of the plasma in MHD equilibrium within this configuration. Instead, the approach used in stellarator optimization is to firstly determine the shape of a closed flux surface for the plasma boundary, which produces an internal configuration with the desired equilibrium properties, such as rotational transform, average magnetic well, average value of β , closed magnetic surfaces and small error

fields, minimization of Pfirsch-Schlüter current, improved confinement of fast ions, etc. Then, calculate the surface current distribution on this surface and the vacuum field in its neighborhood. Finally, find a set of modular field coils that can reproduce it. Naturally, there is no guarantee of the existence of a finite number of isolated coils that can reproduce the required field on the plasma surface and the solution of this complex inverse problem became possible only after the advent of advanced supercomputers (Grieger and Milch, 1993).

The practicability of the modular scheme was tested in the W7-AS device with great success. Stable plasmas were obtained in quasi-steady state at values of $\beta \approx 0.034$, electron temperature $T_e \approx 6.8$ keV at average density $n \approx 2 \times 10^{19} \text{ m}^{-3}$, central ion temperature $T_i \approx 1.7$ keV and energy confinement time $\tau_E \approx 60$ ms (Hirsch et al., 2008). These outstanding results set the ground for the development of W7-X, which is the largest stellarator currently in operation (Gasparotto et al., 2005). The W7-X stellarator was developed at the Max-Planck-Institut für Plasmaphysik, in Greifswald, Germany, and produced its first plasma discharge in 2015 (Wolf et al., 2017). Its main parameters are $R_0 = 5.5$ m, $a = 0.55$ m, $B_0 \leq 2.5$ T, with mild shear, i.e., the rotational transform varying from $\iota(0) = 0.8 \rightarrow \iota(a) = 1.0$. Fifty twisted modular superconducting coils are used to produce the helical field, in five magnetic field modules, setting the periodicity in the toroidal direction, Fig. 15D. Since the field produced by these coils has fixed rotational transform, 20 planar and tilted superconducting coils are assembled over the modular coils, to allow the radial adjustment of the plasma column and modification of the rotational transform, so that many magnetic configurations can be realized. A special feature of W7-X is the availability of localized magnetic island divertors, a concept tested in W7-AS, for controlled power and particle exhaust. The results of W7-X in the first phase of operation with these divertors have been recently reported (Wolf et al., 2019). High density and high performance plasmas were produced, with the following parameters $n \approx 8 \times 10^{19} \text{ m}^{-3}$, $T_e \approx T_i \approx 3.4$ keV, $\beta \approx 0.05$, $\tau_E \approx 0.235$ s. In its peak performance, W7-X achieved a fusion parameter $n\tau_E T_i \approx 6.4 \times 10^{19} \text{ m}^{-3} \cdot \text{keV} \cdot \text{s}$, setting the current record for stellarators (Klinger, 2018; Klinger et al., 2019).

Quasisymmetric configurations

Recently, there has been renewed and intense activity related to the development of “quasisymmetric stellarators” (Helander, 2014). In a quasisymmetric configuration, the variation of $|B|$ along the field is the same for all field lines on a magnetic surface. In such a configuration, the radial drift of particles trapped in local minima of $|B|$ would be reduced, improving confinement, and, as already mentioned, the Pfirsch-Schlüter current would be minimized. Hence, if non-axisymmetric toroidal magnetic fields with quasisymmetry can be produced with technically viable coil systems, these configurations offer the possibility of developing stellarators with stable and efficient high-temperature plasma confinement.

Reversed-field pinch

As mentioned in “Magnetic confinement basics” section, one major instability in current-carrying plasmas is the kink instability, which produces helical distortions of the plasma column. A particular class of these modes are called external kink modes because the rational surface in which the helicity of the equilibrium field lines matches that of the perturbation lies outside the plasma column (Lao, 2020). The most worrisome of them is the $m = 1$, $n = 1$ mode, which corresponds to a helical perturbation that closes on itself after one turn in both poloidal and toroidal directions. Because of this instability, tokamaks normally operate with $q_a > 2$, to avoid the most dangerous modes. Since the poloidal field at the edge of the plasma column is proportional to the plasma current, $B_a \propto I_p$, it follows from Eq. (5) that the value of q_a decreases as the plasma current increases. What would happen then, if the value of the toroidal magnetic field, $B_T = B_\phi \hat{e}_\phi$, was held fixed and the plasma current rapidly increased, so that the $q_a = 1$ threshold was crossed from above? In a standard tokamak, this would trigger a violent instability that would disrupt the plasma column. In the Reversed-Field-Pinch, RFP, configuration, this evolution is prevented by the presence of a highly conductive shell closely fitting the vacuum chamber, which acts as a toroidal flux conserver and imposes that the perpendicular magnetic perturbation associated with the mode vanishes at the boundary, at least for a time of the order of the resistive skin time. A large turbulent state then sets in at the plasma edge, and through a nonlinear process called the dynamo effect, associated with a coherent combination of magnetic field and fluid velocity perturbations, an average poloidal current is driven inside the plasma boundary, reversing the edge toroidal magnetic field.

The first experiments on the pinch effect were initiated over 80 years ago (Bennett, 1934). The first pinches were highly unstable but, after the theoretical work on the kink mode, the concept of toroidal stabilized pinch evolved, with the introduction of the stabilizing toroidal magnetic field. With this scheme, grossly stable toroidal plasma columns were produced, but still with many residual instabilities and poor particle and energy confinement (Bodin and Newton, 1980). Further theoretical work indicated that, when current and pressure gradients were considered, many other unstable modes could be excited and, to avoid them, the equilibrium magnetic field lines had to be highly sheared (Goedbloed and Poedts, 2004). In a pedestrian explanation, this condition can be understood by considering the tension of the magnetic field lines embedded in a conducting fluid. When a fluid perturbation distorts the field lines, there is a restoring magnetic force due to the magnetic field tension. If the equilibrium field lines are shearless, the restoring force is minimized, and the perturbation can protrude across them without much resistance. However, if the equilibrium magnetic field lines are highly sheared, the perturbation, which is excited on a rational surface, encounters an increasing restoring force as it moves away from it and can be avoided if the shear of the field lines is sufficiently high. Actually, experimental data from the Zeta experiment indicated that, in some cases, and after an initial highly turbulent phase, the plasma spontaneously evolved to a short quiescent phase with quite high shear and reversal of the toroidal magnetic field at the plasma boundary, a RFP configuration (Bodin and Newton, 1980). A theoretical model to explain the conditions under which the self-reversal occurs, and the quiescent phase is achieved, was put forward by J.B. Taylor in a seminal publication (Taylor, 1974).

During the turbulent phase, resistive instabilities tear the field lines apart and reconnect them, changing the magnetic topology. This effect and microturbulence forces the plasma to relax towards an equilibrium state. The basic argument of Taylor was that, if the dissipation is weak, so that the plasma is not too far from a perfectly conducting fluid, and in the presence of an external conducting shell, the final equilibrium state can be derived by minimizing the total plasma energy, W_p , subjected to the constraint that the magnetic field helicity K over the total plasma volume remains invariant, that is,

$$K = \int \mathbf{A} \cdot \mathbf{B} \, dV = \text{const} \quad (17)$$

where $\mathbf{A}$ is the vector potential and the integral is over the entire plasma volume. The result of the minimization procedure is that the relaxed equilibria must be in a force-free state, satisfying the equilibrium equation $\nabla \times \mathbf{B} = \mu \mathbf{B}$ where μ is a constant with the same value on all field lines. Solving this equation in the cylindrical approximation for the toroidal plasma column, i.e., $A = R_0/a > 1$, $B_\phi = B_z(r)$; $B_\theta = B_\theta(r)$, and $B_r = 0$, one obtains that the equilibrium magnetic field components are given by Taylor and Newton (2015).

$$B_z = B_0 J_0(\mu r) \quad \text{and} \quad B_\theta = B_0 J_1(\mu r) \quad (18)$$

where $J_n(\mu r)$ are Bessel functions. It follows from this solution that the condition for spontaneous reversal of the toroidal field is $\mu a \geq 2.4$. These theoretical profiles are well reproduced by the experimental ones, as shown in Fig. 16A (Bodin, 1990; Marrelli et al., 2020).

Unfortunately, in the first RFPs, the minimum energy state achieved after the turbulent phase did not have good energy confinement, over most of the plasma cross section, and the values of relevant plasma parameters, such temperature and density, remained rather low as compared to the results obtained in tokamaks. The main reason for this is associated with the profile of the safety factor, which, in the cylindrical approximation, can be written as $q = r B_z / (R_0 B_\theta)$. Therefore, for the Taylor relaxed state, its value at the magnetic axis is $q_0 = 2/(\mu R_0) = 2a/(2.4 R_0)$ in the condition of field reversal. For values of the aspect ratio of standard RFPs, $R_0/a \approx 4$, as in RFX-mod, one obtains $q_0 \approx 0.2$, and the q -profile decreases monotonically to zero at the plasma boundary, as depicted in Fig. 16B. Consequently, inside the plasma, the rational surfaces $q = m/n$ occur for $m = 1$ and monotonically increasing large values of the toroidal mode number n , so that they tend to get densely crammed towards the plasma boundary. Due to the finite resistivity of the plasma, an instability called tearing mode develops at these internal rational surfaces (Lao, 2021), breaking up magnetic field lines and reconnecting them to form helical magnetic islands, as the one sketched in Fig. 14. A spectrum of these modes, with different values of toroidal mode numbers, then emerges, with nonlinear saturated amplitudes $\tilde{b}/B_\theta = 0.01$. It turns out that the associated fluid velocity perturbations, $\tilde{\mathbf{u}}$, have a non-zero correlation with the magnetic field perturbations, giving rise to a mean field electric field $\langle \tilde{\mathbf{E}} \rangle = -\langle \tilde{\mathbf{u}} \times \mathbf{b} \rangle$, which drives the poloidal current responsible for reversing the toroidal field. This regime is called a Multiple Helicity (MH) state. Unfortunately, the magnetic islands tend to overlap close to the plasma boundary in this regime, leading to a large region of stochastic magnetic field lines, spoiling confinement and increasing transport.

For many years, this undesirable feature was considered intrinsic to the dynamo self-organization process, which sustains the field reversal in quasi-steady state. A change of paradigm occurred as result of advanced numerical simulations and substantial improvement on systems to actively control the magnetic field perturbations at the plasma boundary. From these efforts, the possibility of a chaos-free configuration emerged, where the dynamo effect is provided by nonlinear evolution of the innermost $m = 1$ resistive mode that dominates over the others. Quasi-Single Helicity (QSH) states were first obtained in different RFPs, about 20 years ago (Escande et al., 2000). An example of a transient QSH is shown in Fig. 17. The formation of a predominant magnetic island is quite evident in the tomographic image of soft X-ray emission. The MH state is characterized by the poloidally symmetric emissivity in a central region, where enhanced energy and particle transport are indeed compatible with strong magnetic chaos. The QSH state, on the other hand, is characterized by a hot $m = 1$, $n = 8$ island and the spectrum predominance of this mode is evident from measurements made with pick-up coils outside the plasma.

R is the radial coordinate measured from the torus major axis. (C and D) The same quantities during a spontaneous QSH state (No. 11407, $t = 35.8$ ms) with dominant mode $m = 1$, $n = 8$. Reproduced from Fig. 1 of Escande DF, Martin P, Ortolani S, Buffa A, Franz P, Marrelli L, Martinez E, Spizzo G, Cappello S, Murari A, Pasqualotto R and Zanca P (2000) Quasi-single-helicity reversed-field-pinch plasmas. *Physical Review Letters* 85: 1662–1665. <https://link.aps.org/doi/10.1103/PhysRevLett.85.1662>.

A further improvement in producing chaos-free configurations was achieved in the RFX-mod device, by employing a quite advanced feedback system to control the radial component of the magnetic field perturbations at the plasma boundary and operating at high plasma currents $I_p \geq 1$ MA (Lorenzini et al., 2009). According to the authors, as the current is raised, the QSH state becomes purer and, above a threshold of about 4% in the dominant mode normalized amplitude, the separatrix X-point of its magnetic island merges with the main magnetic axis, and the two disappear. The former island O-point becomes the only magnetic axis, and a helical plasma column is formed, with a helical magnetic axis. This new regime, dubbed Single-Helical-Axis (SHAx) state, besides being an outstanding advancement in fusion research, certainly can be considered a paradigmatic example of self-organization in a complex physical system. In the SHAx state, the anomalous transport is substantially reduced, in comparison with the MH state, and reasonable values of the plasma parameters are obtained, as shown in Fig. 18.

The achievement of the QSH and SHAx states has opened new perspectives for the viability of the RFP magnetic confinement configuration for a fusion reactor, somewhat bridging the tokamak and stellarator concepts. Furthermore, the development of successful active control of radial magnetic perturbations at the plasma boundary made it less demanding the requirements for the external conducting shell, what simplifies practical reactor design. The RFP devices currently in operation and their main parameters are shown in Fig. 19.

Compact tori

From an engineering perspective, it would be quite attractive to have a fusion device without toroidal field coils interlocking with the plasma column, so that the plasma would be contained in a simply connected vacuum vessel. Such configurations with toroidal and poloidal magnetic fields of the same order, as in RFPs, are called spheromaks. The configurations without a toroidal field are called Field-Reversed Configurations (FRC). Sketches of the two configurations and associated fields are shown in Fig. 20 (Woodruff et al., 2010).

The spheromak resembles a compact RFP and indeed the plasma is normally formed in a relaxation process, preserving magnetic helicity, towards a Taylor equilibrium state, where the plasma current is nearly parallel to the magnetic field lines. Therefore, it is expected to be globally stable to MHD modes, although error fields and magnetic perturbations can lead to field line stochastization

Fig. 18 (A) Typical electron temperature profile measured in $I_p \approx 1.5$ MA discharges, when the plasma is in a SHaX state. A high-temperature ($T_e = 0.8 - 0.9$ keV) region is present in the core plasma and extends on both sides of the geometric axis. The profile is asymmetric with respect to the geometric axis; however, the gradients in the strong gradient regions (shaded) are different on the two sides. Red and blue refer to the two opposite sides with respect to the helical magnetic axis. A typical profile in the MH state is shown in green for reference. (B) Reconstruction of the full 2D map of the temperature on a poloidal plane, obtained from the dependence of on the geometric coordinates. (A) MST: $A = 1.5/0.5$, $I_{p, max} = 0.6$, $k_B T_e = 2$, $n_e = 1 - 3$. (B) RFX-mod: $A = 2/0.46$, $I_{p, max} = 2$, $k_B T_e = 1.2$, $n_e = 1 - 8$. (C) EXTRAP-T2R: $A = 1.24/0.18$, $I_{p, max} = 0.3$, $k_B T_e = 0.3$, $n_e = 0.5 - 2$. (D) RELAX: $A = 0.5/0.25$, $I_{p, max} = 0.12$, $k_B T_e = 0.3$, $n_e = 0.2 - 3$. (E) KTX: $A = 1.4/0.4$, $I_{p, max} = 0.5$, $k_B T_e = 0.3$, $n_e = 1 - 10$.

and loss of good confinement. The FRC, on the other hand, has a weak or no toroidal field, and the cross-section of the plasma column is bounded by a separatrix, with two hyperbolic stagnation points, outside which the field lines are open, and with an elliptic stagnation point in the confinement region. Contrary to the spheromak, this configuration is highly unstable to MHD instabilities and must be kinetically stabilized by highly energetic ions.

Research on spheromaks, although not in the front line of fusion research, has attracted much attention in recent years as its basic physics is akin to astrophysical processes, such as coronal mass ejection in the inner heliosphere (Singh et al., 2020). Stabilized FRCs are still being pursued as a viable fusion scheme because they can be translated along the axis of a linear configuration, merged, and adiabatically compressed (Binderbauer et al., 2010). Therefore, they are quite suitable for pulsed, high density approaches to fusion.

Glossary

Langmuir waves Langmuir waves (also called plasma waves) are longitudinal electrostatic waves that propagate in a plasma because of variations in plasma electron density. Their frequency is close to the electron plasma frequency ω_{pe} . When accounting for electron temperature, their wavelength and frequency obey the Bohm-Gross dispersion relation, leading to wavelengths of order of the Debye length λ_{De} .

Adiabatic theory Adiabatic theory deals with systems characterized by variables which evolve slowly as compared to others. Perturbation theory can then be used to derive so-called adiabatic invariants, i.e. variables which remain approximately constant when changes occur slowly. In controlled fusion plasmas, electrostatic turbulence develops on time scales much longer than the ion (hence electron) cyclotron motion. The associated adiabatic invariant is the magnetic moment $\mu_s = m_s v_{cs}^2 / 2B$ with v_{cs} the velocity associated to the cyclotron motion.

Frenet frame The Frenet frame is an orthogonal basis associated to any continuous and differentiable curve in the 3-dimensional Euclidian space. Its three basis vectors are the tangent **T**, the normal **N** and the binormal **B** (Fig. 5). **T** points in the direction of motion. **N** relates to the derivative of **T** with respect to the curvilinear coordinate s , i.e. the arclength parameter of the curve. **B** is the cross product of **T** and **N**. The Frenet-Serret formulas state that $d\mathbf{T}/ds = \mathbf{N}/R_C$, $d\mathbf{N}/ds = -\mathbf{T}/R_C + \mathbf{B}/R_T$, $d\mathbf{B}/ds = -\mathbf{N}/R_T$, with R_C and R_T the curvature and torsion radii, respectively.

Improved confinement regimes Improved confinement regimes refer to plasma scenarios where the energy confinement time is enhanced as compared to the naturally turbulent plasma state, as a result of plasma self-organization. They are associated with the development of weaker turbulent cross-field transport—usually of density, temperature or both—on a radially localized region. These regions are characterized by transport barriers, i.e. large gradients of density and/or temperature. Several physical parameters have been identified as key to bifurcate towards such regimes, such as a sheared radial electric field, the twist of helical field lines (the safety factor) or the ion to electron temperature ratio.

Lagrangian (or material) derivative The Lagrangian (or material) derivative deals with systems which are subject to a space-and-time-dependent macroscopic velocity field $\mathbf{u}(\mathbf{x}, t)$. It is defined as the rate of change with time of some physical quantity (denoted Q hereafter, e.g. density, velocity, pressure, etc.) in the co-moving frame of the flow, i.e. when moving along with the fluid. It reads as follows: $dQ/dt = \partial Q/\partial t + \mathbf{u} \cdot \nabla Q$. Conversely, the Eulerian time derivative, which reduces to $\partial Q/\partial t$, is taken in the laboratory frame.

Fokker-Planck operator A Fokker-Planck operator refers to the partial differential equation which obeys the probability density function of a particle velocity or position under the influence of drag and random forces, as in Brownian motion. In hot and dilute plasmas, it describes the general form taken by the Coulomb collision operator, made of both convection and diffusion terms in the velocity phase space.

Grad-Shafranov equation The Grad-Shafranov equation derives from the static magneto-hydrodynamical (MHD) equilibrium of axi-symmetric tokamak plasmas, balancing the pressure gradient with the Lorentz force. It relates a generalized Laplacian of the poloidal magnetic flux—which labels magnetic flux surfaces—to the pressure gradient and to the stream function of the plasma current and its derivative.

Chapman-Enskog theory The Chapman-Enskog theory provides an asymptotic closure scheme for neutral gas dominated by collisions. It proceeds by expanding the distribution function, order by order, in the small parameter defined by the ratio of the collisional mean free path over the variation length scale of macroscopic quantities.

Markovian processes Markovian processes characterize the time evolution of systems in which the transition probability from one configuration in the phase space to another only depends on these two configurations themselves, and not of the past history of the system. Brownian motion—which characterizes the random motion of particles suspended in a fluid resulting from their collision with the fast-moving molecules in the fluid—is an example of such a process.

Onsager symmetry Onsager symmetry, or Onsager reciprocal relation, states that, in systems at local thermodynamical equilibrium, certain pairs of flows and forces are related by the same coefficients. When thermodynamical forces of the system are properly identified—such that the entropy production rate is the sum of the scalar products of these forces with their associated flows—the transport matrix which relates flows to forces is then symmetrical.

Introduction

This chapter introduces the basic characteristics of hot magnetized plasmas encountered in controlled fusion devices. Section “**Introduction**” reviews the typical length and time scales for ITER plasmas as an example, highlighting the existence of several small dimensionless parameters. Section “**Characteristic length and time scales in fusion plasmas**” explains why particle trajectories are well confined in the magnetic configuration of tokamaks. Especially, fast and slow motions are distinguished within the frame of the adiabatic theory, the latter leading to secular drifts transverse to the magnetic field lines. Two classes of particles are also identified, passing and trapped. Section “**Particle orbits in tokamak geometry**” details the two main descriptions of these hot plasmas, namely kinetic and fluid. Both can be simplified in the framework of the adiabatic theory, leading to the gyrokinetic theory and fluid drifts, respectively. The magneto-hydrodynamical description is introduced as a subset of the fluid one. The last section, Section “**From (gyro-)kinetic to fluid and MHD descriptions**,” addresses Coulomb binary collisions and their effects. In particular, the main results of neoclassical theory—dealing with the enhancement of collisional effects due to particle trajectory—are reviewed. Some open prospects regarding non-axisymmetrical configurations closes the section.

Characteristic length and time scales in fusion plasmas

The various processes taking place in fusion plasmas develop at different length scales which span a large number of orders of magnitudes (Fig. 1). It is illuminating to split these characteristic scales in two domains, whether they are larger or smaller than the Debye length, λ_D . λ_D is the characteristic distance at which the electric charge q_s of a given particle of species “s” can be considered screened by the charges of its neighbors. It scales like $\lambda_D = (\epsilon_0 T_s / q_s^2 n_s)^{1/2}$, with ϵ_0 the permeability of free space and T_s and n_s the temperature (in this chapter, temperature refers to thermal energy, i.e. the temperature in Kelvin times the Boltzmann constant k_B). It is expressed in Joules in SI, or in electron-volt, with the conversion $1 \text{ eV} \sim 1.602 \cdot 10^{-19} \text{ J}$ and particle density of the “s” species. The Debye length ranges from typically $9 \cdot 10^{-5} \text{ m}$ in the core of an ITER deuterium plasma ($n \sim 10^{20} \text{ m}^{-3}$, $T \sim 15 \text{ keV}$) down to about $3 \cdot 10^{-5} \text{ m}$ at its periphery, at the last closed magnetic surface ($n \sim 2 \cdot 10^{19} \text{ m}^{-3}$, $T \sim 300 \text{ eV}$).

Another important property of this scale can be estimated from the Maxwell-Gauss equation, which relates the Laplacian of the electric potential ϕ to the charge density: $(\lambda_D/L)^2 (e\phi/T_0) = (\sum_i Z_i n_i - n_e)/n_0$, with L the characteristic gradient length scale of ϕ , and n_0 , T_0 the relevant density and temperature. The subscripts “i” and “e” stand for ions and electrons, and Z the atomic number. Fusion plasmas are kinetic, in the sense that their kinetic energy much exceeds the potential one, so that $e\phi/T_0 < 1$. Then it readily appears that the left hand side vanishes at scales $L \gg \lambda_D$, so that plasmas can be considered quasi-neutral at these large scales. Notice

Fig. 1 Typical length scales in controlled fusion plasmas.

however that this does not preclude the development of any electric potential. It simply states that such a field exhibits large scale variations only.

At distances smaller than λ_{Ds} , particles experience mutual interactions via the Coulomb force, leading to binary collisions. Conversely, at distances larger than λ_{Ds} , particles mainly interact via the mean electromagnetic fields. Hence, λ_{Ds} marks the transition between singular and collective effects. A Debye sphere of radius λ_{Ds} contains approximately $3 \cdot 10^8$ particles in the core of ITER plasmas. Langmuir waves can develop at scales commensurable to λ_{Ds} to restore quasi-neutrality. Their frequency, set by electron inertia, is close to the electron plasma frequency: $\omega_{pe} = v_{Te}/\lambda_{De}$, with v_{Te} the electron thermal speed $v_{Te} = (T_e/m_e)^{1/2}$.

The shortest relevant distance is the one reached by two similar particles interacting frontally. This so-called Landau distance, λ_{Ls} , is reached when their entire kinetic energy is converted into potential energy, namely for $\lambda_{Ls} = q_s^2/4\pi\epsilon_0 T_s$. It is of the order of 10^{-13} m for both thermal electrons and hydrogenous ions in the core of ITER plasmas. It happens to be much larger than the acting distance of the weak nuclear force, of order of 10^{-15} m. The nuclear force ensures the nucleons—protons and neutrons—remain bounded within the nucleus. As a matter of fact, similarly to what happens in stars—although involving a different fusion reaction in this case, namely proton-proton—deuterium-tritium fusion reactions are essentially governed by quantum physics and the tunneling effect in tokamak plasmas. This shortest distance of interaction is much smaller than the average distance between two particles, sometimes called the Loschmidt distance $\lambda_{\mathcal{L}s} = n_s^{-1/3}$, of the order of 2×10^{-7} m in the ITER plasma core. The very large ratio $\lambda_{\mathcal{L}s}/\lambda_{Ls} \gg 1$ between the inter-particle distance and the minimal approach distance highlights that the vast majority of Coulomb binary collisions are grazing, i.e. leading to small angle deflections. This justifies a statistical approach of elastic collisions. The collision frequency—defined as the inverse time for a particle to have its velocity vector deflected by about 90 degrees—typically scales like $\nu_{coll,s} \sim n_s T_s^{-3/2}$. It is of the order of 10^4 s^{-1} for electron-electron and electron-ion collisions. The typical mean free path of both thermal ions and electrons in the core of ITER is of the order of 5 km, i.e. about 100 turns around the symmetry axis along the magnetic field lines—lines tangent to the magnetic field $\mathbf{B}$. As far as inelastic collisions, giving birth to fusion reactions, are concerned, these occur at a much lower frequency.

Controlled fusion plasmas are magnetized, so that each charged particle experiences a cyclotron motion at leading order (cf. next section). This is actually the primary essence of particle confinement. The cyclotron radius ρ_{cs} of their helical motion around magnetic field lines scales as the inverse of B : $\rho_{cs} = m_s v_{cs}/q_s B$, with v_{cs} the velocity transverse to $\mathbf{B}$. It is of the order of 3 mm for thermal deuterium ions and of 0.05 mm for thermal electrons in ITER core plasmas, i.e. in the ratio of the mass ratio square root. These lengths transverse to the magnetic field are much smaller than the minor radius of the configuration, which can be as large as a few meters: $\rho^* = \rho_{cs}/a \ll 1$. The same hierarchy holds for fusion-born alpha particles of 3.56 MeV, which have a gyro-radius of about 3.6 cm. The gyro-frequency scales like $\omega_{cs} = q_s B/m_s$. It is of order $40 \cdot 10^6 \text{ rad s}^{-1}$ for deuterium and $150 \cdot 10^9 \text{ rad s}^{-1}$ for electrons (i.e. in the range of ω_{pe}), so that the time scale associated with the cyclotron motion is much smaller than any other relevant characteristic time in controlled fusion plasmas, including electrostatic turbulence, which usually develops at frequencies in the range of a few to a few hundreds of kilohertz. This property is the backbone of the adiabatic theory developed in the next section.

Some other length and time scales are encountered when magnetic fluctuations enter into play. These can propagate along magnetic field lines at the Alfvén speed, v_A , which is the ion thermal velocity divided by the square root of the beta parameter, the ratio of the plasma pressure to the magnetic energy $\beta = nT/(B^2/2\mu_0)$, with μ_0 the permittivity of free space: $v_A = v_{Ti}/\beta^{1/2}$. It is of the order of the electron thermal velocity. In this case, small scale structures may develop in the plane transverse to $\mathbf{B}$, of the order of the collisionless electron skin depth, $d_e = c/\omega_{pe}$, i.e. in between the electron and the ion gyro-radii.

From this rapid overview, it appears that hot magnetized plasmas experience collective effects at spatial and time scales much smaller than those of the system, which correspond to a few meters and a few seconds—the latter referring to the energy confinement time. This hierarchy has long been advocated to address those processes on the basis of scale separation. Growing evidence shows, however, that plasma self-organization develops at intermediate—or *meso*—scales which fill the gap, hence justifying an equal footing treatment of small and large scales.

Particle orbits in tokamak geometry

The adiabatic framework of magnetized plasmas

In controlled fusion devices like tokamaks and stellarators, the cyclotron motion exhibits time and spatial scales much smaller than those characterizing the guiding magnetic field. They are typically in the range $1/(\omega_{ci}\tau_R) \sim 10^{-8} \ll 1$ and $\epsilon = \rho_{ci}/R \sim 10^{-3} \ll 1$, with τ_R the resistive diffusion time of the plasma current, as an estimate of the B-field evolution time, and R the major radius of the toroidal device. The same holds for the time evolution of the electric field, although its time evolution can be much shorter than τ_R when accounting for turbulence dynamics: $\omega_{turb}/\omega_{ci} \sim 10^{-3} \ll 1$. In this limit, plasma particles are magnetized, so that their motion can be decomposed into a fast gyromotion around the magnetic field lines, $\mathbf{v}_c = \boldsymbol{\omega}_{cs} \times \boldsymbol{\rho}_{cs}$, plus the motion of the gyro-center, $\mathbf{v}_{Gs}$.

Transverse drifts and parallel acceleration

Discriminating the secular drift of the particles across the magnetic field lines from their fast gyromotion is performed in the framework of the adiabatic theory. There, the electric and magnetic fields are decomposed into their average over the gyro-motion, $\langle \mathbf{B} \rangle$ and

$\langle \mathbf{E} \rangle$, plus perturbations, $|\delta \mathbf{B}| \ll B$ and δE . Decomposing the velocity in the same way, $\mathbf{v}_s = \langle \mathbf{v}_s \rangle + \delta \mathbf{v}_s$, Newton's law can then be split into average and fluctuating parts. At leading order in the small parameters mentioned above, the fluctuating part leads to the cyclotron motion governed by the averaged magnetic field, $\langle \mathbf{B} \rangle$. When magnetic turbulence is negligible, $\langle \mathbf{B} \rangle$ can be approximated to its value at the position of the gyro-center: $\langle \mathbf{B} \rangle \approx \mathbf{B}(\mathbf{x}_G) = \mathbf{B}_G$. The averaged part of Newton's law involves, in particular, the non-vanishing quadratic term $\langle \delta \mathbf{v}_s \times \delta \mathbf{B} \rangle$ coming from the Lorentz force. As already stated, $\delta \mathbf{v}_s = (q_s \mathbf{B}_G / m_s) \times \boldsymbol{\rho}_{cs}$, and $\delta \mathbf{B}$ is simply obtained by Taylor expanding the magnetic field at leading order from the gyro-center to the particle position: $\delta \mathbf{B} = (\boldsymbol{\rho}_{cs} \cdot \nabla) \mathbf{B}_G$. The nonlinear term can then be evaluated in terms of the averaged quantities only, by noticing that solely $\boldsymbol{\rho}_{cs}$ depends on the gyro-phase. It leads to $\langle \delta \mathbf{v}_s \times \delta \mathbf{B} \rangle \approx -(\mu_s / q_s) \nabla B_G$, where $\mu_s = m_s v_{cs}^2 / 2 B_G$ is the magnetic moment, which will be shown to be an adiabatic invariant in the following subsection. The resulting dynamical equation governing the average velocity $\langle \mathbf{v}_s \rangle$, i.e. that of the gyro-center $\langle \mathbf{v}_s \rangle = \mathbf{v}_{Gs}$, then reads as follows:

$$m_s d\mathbf{v}_{Gs}/dt = q_s (\langle \mathbf{E} \rangle + \mathbf{v}_{Gs} \times \mathbf{B}_G) - \mu_s \nabla B_G \quad (1)$$

It readily appears that the gyro-center experiences a novel force in addition to the Coulomb and Lorentz ones, due to the weak inhomogeneity of the magnetic field at the scale of the cyclotron radius. One can proceed further by decomposing the velocity in terms of parallel and transverse components: $\mathbf{v}_{Gs} = \mathbf{v}_{G//s} + \mathbf{v}_{G\perp s}$. Injecting this decomposition in Eq. (1) allows one to retrieve the expressions of the transverse drifts on the one hand, and of the parallel acceleration on the other hand.

Projecting Eq. (1) on the transverse plane, i.e. in practice subtracting its parallel component, leads to 2 terms on the left hand side: $(d\mathbf{v}_{G\perp s}/dt)_\perp$ on the one hand, and $(\mathbf{v}_{G//s} d\mathbf{b}/dt)_\perp$ on the other hand. The first term can be neglected at leading order; indeed, it is much smaller than the Lorentz term on the right hand side. The second term can be approximated by $(v_{G//s}^2 db/ds)$, with "s" the curvilinear abscissa along the magnetic field lines and $\mathbf{b} = \mathbf{B}_G/B_G$ the unit vector along the field lines. The latter term can be evaluated using the Frenet frame, which tells that $d\mathbf{b}/ds = \mathbf{N}/R$, with $\mathbf{N}$ the unit vector normal to the field lines, and R the curvature radius of these lines—which is nothing but the major radius of the torus. Then, cross-multiplying the transverse projection of Eq. (1) provides the expression of the transverse drifts at leading order (cf. Fig. 2A):

$$\mathbf{v}_{G\perp s} = (\langle \mathbf{E} \rangle \times \mathbf{B}_G) / B_G^2 + (1/q_s B_G^2) \mathbf{B}_G \times [\mu_s \nabla B_G / B_G + m_s v_{G//s}^2 \mathbf{N} / R] \quad (2)$$

The first component is the electric drift $\mathbf{v}_E$. It does weakly depend on the species, due to the fact that $\langle \mathbf{E} \rangle$ is averaged over a cyclotron radius. Therefore, it carries a limited amount of current in the transverse direction. The resulting current is mostly carried by the ions, for they have a larger gyro-radius. This drift leads to particle convection. It is also responsible for turbulent transport of particles, momentum and heat when the electric field develops a broad spectrum of turbulent fluctuations. The two last components constitute the magnetic drifts $\mathbf{v}_{ds}$: the grad-B and curvature drift, respectively. The latter results from the centrifugal force associated with the parallel motion along curved field lines. It can be recast differently by noticing that $\mathbf{N}/R = \mathbf{b} \cdot \nabla \mathbf{b} = (\nabla \times \mathbf{B}_G) \times \mathbf{b} / B_G + (\nabla_\perp B_G) / B_G$. Then the last two terms of Eq. (2) can be recast as follows: $\mathbf{v}_{ds} = (m_s v_{G//s}^2 + \mu_s B_G) \mathbf{B}_G \times \nabla B_G / (q_s B_G^3) + m_s v_{G//s}^2 (\nabla \times \mathbf{B}_G)_\perp / (q_s B_G^2)$. The last term of this expression, proportional to the transverse plasma current—hence to the pressure gradient through the magneto-hydrodynamical equilibrium—is small in low-beta plasmas. In turn, $\mathbf{v}_{ds}$ is mainly vertical in tokamak plasmas ($\mathbf{B}_G$ is mainly toroidal and ∇B_G is horizontal, pointing toward the symmetry axis). It results from the small deformation of the cyclotron radius in the presence of an inhomogeneous magnetic field, so that the cyclotron orbit is not exactly a close loop in

Fig. 2 (A) Charged particle motion in a strong and inhomogeneous magnetic field ($\rho_{ci}/R \sim 10^{-2}$ here). (B) The $\mathbf{B} \times \nabla B$ drift originates from the not perfectly circular cyclotron orbit. (C) Sketch illustrating the origin of the diamagnetic fluid drift velocity (case of constant temperature).

the transverse plane (cf. Fig. 2B). Ions drift in one direction, electrons in the other, leading to vertical charge separation. This current carried by the gyro-centers is only part of the total transverse plasma current. Indeed, it is to be added to the magnetization current carried by the particles themselves in their cyclotron motion. This point will be made clear when comparing kinetic and fluid approaches (cf. Section “Particle orbits in tokamak geometry”).

Getting the parallel acceleration requires in particular to derive the parallel projection of the time derivative of the transverse drifts. After some lengthy yet straightforward calculation, one finally obtains:

$$m_s dv_{G//s}/dt = \left[\mathbf{b} + \left(m_s v_{G//s} / q_s B_G \right)^2 (\nabla \times \mathbf{B}_G)_{\perp} \right] (q_s \langle \mathbf{E} \rangle - \mu_s \nabla B_G) + \left(m_s v_{G//s} / B_G^3 \right) (\mathbf{B}_G \times \nabla B_G) \langle \mathbf{E} \rangle \quad (3)$$

As discussed previously, the term proportional to the transverse current $(\nabla \times \mathbf{B}_G)_{\perp}$ is smaller than the other ones in the ratio β . All the other terms are a priori of the same order of magnitude. The parallel forces contained in the first terms on the right hand side can lead to particle trapping (cf. section “Passing and trapped particles”) due to either the inhomogeneity of the magnetic field or of the electric field along the field lines. The last term results from a synergy between the electric field and the B-field inhomogeneity.

In summary, the velocity of a particle immersed in a strong and weakly varying magnetic field—with respect to the cyclotron motion—can be decomposed in three components, made up of the cyclotron motion and the parallel and transverse components of the gyro-center motion: $\mathbf{v}_s = \mathbf{v}_{cs} + \mathbf{v}_{G//s} + \mathbf{v}_{G\perp s}$.

The three motion invariants

At equilibrium—as will be shown hereafter, equilibrium means here axisymmetry and time-independent scalar and vector electro-magnetic potentials—particle motion in tokamak plasmas is characterized by three motion invariants, i.e. scalar quantities which are conserved along individual trajectories. As a consequence, the motion is said to be integrable. Moreover, the existence of three periodic directions (the two angles of the torus plus the cyclotron phase) ensures that the motion is confined in a finite volume. This is the essence of particle confinement in tokamaks.

The energy ϵ_s . Let us perform the scalar product of Newton’s law ($m_s d\mathbf{v}/dt = q_s (\mathbf{E} + \mathbf{v} \times \mathbf{B})$) with the velocity $\mathbf{v}$. The Lorentz force, transverse to $\mathbf{v}$, disappears from the right hand side. If the scalar ϕ and vector $\mathbf{A}$ potentials do not explicitly depend on time, then the right hand side reads as follows: $\mathbf{v} \cdot \mathbf{E} = -\mathbf{v} \cdot \nabla \phi = -d\phi/dt$, with d/dt the Lagrangian derivative taken along the trajectory. Then, it readily follows that $d\epsilon_s/dt = 0$, with $\epsilon_s = m_s v^2/2 + q_s \phi$ the energy of the particle.

The magnetic momentum μ_s . It can be shown that, within the frame of the adiabatic theory, one can construct a magnetic momentum which gets conserved at all orders of the small parameter ϵ . We propose here a simplified demonstration at order one in ϵ . Let us consider the time evolution of the transverse energy $d(\mu_s B_G)/dt$. From the invariance of the energy, this term is straightforwardly related to the parallel acceleration and to the time derivative of the electric potential: $d(\mu_s B_G)/dt = -m_s v_{G//s} dv_{G//s}/dt - q_s d\phi/dt$. Using Eq. (3), one can show after some algebra that $d(\mu_s B_G)/dt = \mu_s dB_G/dt$. The conclusion is that $d\mu_s/dt = 0$, so that $\mu_s = m_s v_{cs}^2/2B_G$ is an adiabatic invariant of motion.

The toroidal kinetic momentum $P_{\phi s}$. At first approximation—especially when ignoring the finite number of toroidal field coils—and in the absence of turbulence, tokamak plasmas can be considered axisymmetric. All quantities are thus independent of the toroidal angle ϕ . The Noether theorem tells us that such a symmetry is associated to an invariant. This directly derives from the Lagrange equations, stating that $d[\partial L/\partial(q_i/dt)]/dt - \partial L/\partial q_i = 0$, with L the Lagrangian and q_i the generalized coordinates. The invariant associated to axisymmetry $\partial L/\partial \phi = 0$ is the toroidal kinetic momentum P_{ϕ} , which then reads $P_{\phi} = \partial L/\partial(d\phi/dt)$. Using the expression of the Lagrangian of a charged particle in an electromagnetic field $L_s = m_s v_s^2/2 - q_s \phi + q_s \mathbf{v} \cdot \mathbf{A}$ and noticing that $d\phi/dt = v_{\phi s}/R$, one readily finds $P_{\phi s} = m_s R v_{\phi s} + q_s R A_{\phi}$. The latter term can be related to the poloidal magnetic flux ψ , which is a label of the flux surfaces. In the end, one obtains $P_{\phi s} = m_s R v_{\phi s} + q_s \psi$. One consequence is that particle trajectories are not contained within magnetic flux surfaces—which would have been the case if ψ would have been the invariant. Yet, their distance from these surfaces remains small, scaling like the cyclotron radius, among others.

In summary, particle motion is characterized by three invariants in tokamaks at equilibrium: the energy ϵ_s provided the scalar and vector potentials do not depend explicitly on time, the magnetic momentum μ_s within the adiabatic framework, and the toroidal kinetic momentum $P_{\phi s}$ in the axisymmetric limit. Because they break the equilibrium conditions, turbulence and collisions break these invariances, hence leading to the breaking of confinement through cross-field transport.

Passing and trapped particles

The parallel acceleration Eq. (3) is primarily governed by the B-field inhomogeneity $\nabla_{//} B_G$. B_G decreasing like $1/R$, those particles with insufficient parallel energy will loop back before reaching the innermost poloidal angle, $\theta = \pi$, on the magnetic surface where the magnetic field is maximum, $B_{\max}$. These are called ‘trapped’ particles—the others being ‘passing.’ Their main characteristics can be simply derived from the motion invariants.

Let us consider a simple circular and concentric magnetic equilibrium where $B(r, \theta) = B_0 R_0/R$, with B_0 and R_0 the magnetic field and major radius on the outer mid-plane, at $\theta = 0$, and $R = R_0(1 + \epsilon \cos \theta)$. Here, $\epsilon = r/R_0$ the inverse of the aspect ratio will be considered as a small parameter, $\epsilon \ll 1$ (limit of large aspect ratio $R/a \gg 1$). Let us also neglect the potential energy, which is much smaller than the kinetic energy. The parallel velocity of the gyro-center then reads: $v_{G//s}^2 = (2/m_s)(\epsilon_s - \mu_s B)$. It appears that $v_{G//s}$ vanishes if ϵ_s is smaller than $\mu_s B_{\max}$. Performing Taylor expansion in the small parameter ϵ , this inequality can be recast as

follows, giving the trapping condition in terms of the ratio of the parallel and transverse velocities at $\theta = 0$: $(v_{G//s}/v_{cs})_{\theta=0} < (2\epsilon)^{1/2}$. In the same limit and assuming an isotropic Maxwellian distribution function, the fraction f_t of trapped particles is found to be $f_t = 2(2\epsilon)^{1/2}/\pi$.

Trapped particles move back and forth in between their two bouncing points—located at the same distance from the symmetry axis—on the same magnetic surface. Their trajectory has a non-vanishing width in the transverse plane, such that it looks like a banana. This width, δ_{bs} , can be estimated on the equatorial plane by invoking the invariance of $P_{\phi s}$. Indeed, writing that $P_{\phi s}$ has the same value on the inner and outer sides of the banana trajectory at $\theta = 0$, and performing Taylor expansion in the limit $\delta_{bs}/r \ll 1$, one gets: $\delta_{bs} \approx 2m_s R v_{\phi s} / (q_s d\psi/dr)$. The radial derivative of the poloidal magnetic flux depends on the poloidal magnetic field, so that $d\psi/dr = -RB_\theta \approx -rB_\phi/q$ with $q = rB_\phi/RB_\theta$ the safety factor in the cylindrical and large aspect ratio approximation. In the end, the so-called banana width is of the order of $\delta_{bs} \approx 2q\rho_{cs}/\epsilon^{1/2}$, where the toroidal velocity has been approximated by $v_{\phi s} \approx v_{G//s} = (2\epsilon)^{1/2}v_{cs}$, which holds for marginally trapped particles. Performing the same analysis for passing particles would show that their trajectory departs from their reference magnetic surface by the characteristic distance $q\rho_{cs}$ (cf. Fig. 3A).

Using the same relationship between parallel and transverse velocities provides a way to quantify the bouncing frequency ω_{bs} . It is given by the ratio of the parallel velocity over the parallel length in between the two turning points. For thermal particles, one then obtains: $\omega_{bs} \approx \epsilon^{1/2}v_{Ts}/2\pi qR$. Notice that ω_{bs} is much smaller than the cyclotron frequency, in the ratio $\omega_{bs}/\omega_{cs} \approx \epsilon^{1/2}\rho_{cs}/qR \ll 1$.

It turns out that trapped particles also undergo an even slower precession in the toroidal direction. This results from the fact that the magnitude of the parallel velocity is not exactly the same in the inboard and outboard side of the banana orbit due to the inhomogeneity of the magnetic field: $v_{G//s}^2 = (2/m_s)(\epsilon_s - \mu_s B)$, where we recall that ϵ_s and μ_s are motion invariants. This imbalance of the parallel velocity $\Delta v_{G//s} \approx (\mu_s \delta_{bs}/m_s v_{G//s}) dB/dr$ then results in the precession frequency $\omega_{ds} \approx \Delta v_{G//s}/R$ which then reads: $\omega_{ds}/\omega_{cs} \approx (q\rho_{cs}^2/rR) \ll 1$ (cf. Fig. 3B). One can further notice the hierarchy: $\omega_{ds} \ll \omega_{bs} \ll \omega_{cs}$.

Characterizing these various frequencies is an important issue since they can resonate with plasma waves and allow for the resonant transfer of energy between certain classes of particles and waves, possibly leading to instabilities and deleterious transport across the magnetic surfaces. Alternatively, they can be used to transfer energy from injected waves to particles, hence providing a way to heat up the plasma.

From (gyro-)kinetic to fluid and MHD descriptions

One can basically distinguish three levels of description of hot plasmas. In each case, the problem consists in calculating the self-consistent plasma response to electric and magnetic fields. These fields derive from particle charge and current densities via Maxwell's relations.

The most demanding description in terms of numerical resources (memory and computational time), yet the simplest in terms of equations, relies on Newton's law. One follows the motion of each individual particle under the action of the Coulomb and Lorentz forces. This approach is however intractable given the huge number of particles to be considered (of the order of the Avogadro number per species in ITER plasmas). The *kinetic* approach is the second one; it evolves the distribution function—quantifying the average number of particles per elementary volume in the phase space—of each species in the six-dimensional (6D) phase space (3 in position, 3 in velocity). The number of degrees of freedom reduces to six times the number of species. The third description is the *fluid* one, derived from the kinetic one by integrating over the velocity space. In this case, the number of fluid moments is

Fig. 3 (A) Projection on the poloidal cross-section of trapped and passing orbits. (B) Sketch of a trapped trajectory in the (θ, ϕ) plane illustrating the toroidal precession (inset: 3-dimensional view; courtesy D. Zarzoso /R. Varennes, GCT code).

a priori infinite, hence requiring a closure assumption. The two latter descriptions and their refinements are detailed in the following sections.

Vlasov and gyrokinetic equations

The one-particle distribution function $f_s(\mathbf{x}, \mathbf{v}, t)$ of a given species “ s ” measures the density of these particles at time t in an elementary volume of the six-dimensional phase-space centered on the $\mathbf{x}$ position and the $\mathbf{v}$ velocity.

In hot magnetized plasmas such as those encountered in the core of controlled fusion devices, binary Coulomb collisions play a minor role—although not negligible—the collision frequency being much smaller than most of other relevant frequencies (cf. Section “Introduction”). In turn, Vlasov proposed an equation in 1945 where the time evolution of f_s does not depend on binary collisions, the interaction between particles being mediated by the mean electric $\mathbf{E}$ and magnetic $\mathbf{B}$ fields. It states that f_s is constant along the trajectories, i.e. along the flow motion in the 6D phase space which obeys the following equations: $d\mathbf{x}/dt = \mathbf{v}$ and $m_s d\mathbf{v}/dt = q_s(\mathbf{E} + \mathbf{v} \times \mathbf{B})$. Its non-relativistic expression reads as follows:

$$\partial_t f_s + \mathbf{v} \cdot \nabla_{\mathbf{x}} f_s + (q_s/m_s) (\mathbf{E} + \mathbf{v} \times \mathbf{B}) \cdot \nabla_{\mathbf{v}} f_s = 0 \quad (4)$$

It can be derived by performing relevant truncations of the so-called BBGKY hierarchy of equations (after the name of its co-authors, Bogoliubov–Born–Green–Kirkwood–Yvon). There, the time evolution of the $(M-1)$ -particle distribution function can be related to that of the M -particle $f_{M,s}(\mathbf{x}_1, \dots, \mathbf{x}_M, \mathbf{v}_1, \dots, \mathbf{v}_M, t)$, with N the total number of particles and $1 \leq M \leq N$. The procedure relies on truncation of the hierarchical equations, obtained from the partial integration of Liouville’s equation, which is obeyed by the N -particle distribution function f_N .

Although weak, collisions often need to be accounted for, inter alia because they ensure the relaxation towards the Maxwellian distribution function. In this case, the right hand side of Eq. (4) is replaced by a Coulomb collision operator $\sum_{s'} C(f_s, f_{s'})$, where the sum is taken over all species (denoted by s') including the species s which is the subject of Eq. (4). It accounts for particle-particle interactions which take place at typical distances smaller than the Debye length. This intrinsically nonlinear operator can be shown to take the general form of a Fokker-Planck operator. It is often linearized, the distribution functions then being assumed to remain close to a Maxwellian. Several linearized expressions exist in the literature.

In the adiabatic limit which is relevant at least in the core of controlled fusion plasmas, the 6D phase space $(\mathbf{x}, v_{G//s}, \mu_s, \varphi_c)$ can be reduced to a 4D phase space $(\mathbf{x}_{Gs}, v_{G//s})$ plus the adiabatic invariant μ_s , basically by averaging out over the fast gyro-phase φ_c . The resulting *gyrokinetic equation* then involves the 5D distribution function f_{Gs} of the gyrocenters. Its expression looks similar to the Vlasov equation, with the particle flow replaced by that of the gyrocenters at order 1 in ϵ : $d\mathbf{x}_{Gs}/dt = v_{G//s} \mathbf{b} + \mathbf{v}_{G \perp s}$, $d\mathbf{v}_{G \perp s}/dt = 0$ and $dv_{G//s}/dt$ given by Eq. (3) in Section “Characteristic length and time scales in fusion plasmas.” Some refinements have however to be accounted for—which take the form of additional terms in the Jacobian of the transformation—to preserve the necessary Hamiltonian structure of the equation, so that it finally reads:

$$\partial_t f_{Gs} + B_{||}^{*-1} \nabla_{\mathbf{x}} \cdot [B_{||}^* (d\mathbf{x}_{Gs}/dt) f_{Gs}] + B_{||}^{*-1} \partial/\partial v_{G//s} [B_{||}^* (dv_{G//s}/dt) f_{Gs}] = 0 \quad (5)$$

with

$$B_{||}^* (d\mathbf{x}_{Gs}/dt) = v_{G//s} \mathbf{B}^* + \mathbf{b} \times [(\mu_s/q_s) \nabla \mathbf{B} + \nabla \langle \phi \rangle]; B_{||}^* (dv_{G//s}/dt) = -\mathbf{B}^* \cdot [\mu_s \nabla \mathbf{B} + q_s \nabla \langle \phi \rangle] / m_s.$$

and $\mathbf{B}^* = \mathbf{B} + (m_s/q_s) v_{G//s} \nabla \times \mathbf{b}$, $B_{||}^* = \mathbf{B}^* \cdot \mathbf{b}$. Here, the electrostatic limit has been considered, which assumes that the vector potential is constant in time. It is relevant in the plasma core where most of the turbulent transport is due to fluctuations of the electric potential. It appears that the above equations of motion derived from the phase space reduction in the Hamiltonian formalism are identical to those derived from Newton’s law (cf. Section “Characteristic length and time scales in fusion plasmas”) in the limit $(m_s v_{G//s} / q_s B^2) \mu_{0j//} \rightarrow 0$, which is equivalent to approximating $B_{||}^*$ by B . In the core of tokamak plasmas, $(m_s v_{G//s} / q_s B^2) \mu_{0j//}$ is indeed very small, of the order of $(a/qR) \rho^* \sim 10^{-3}$ for thermal ions in ITER.

Self-consistently solving the gyrokinetic Eq. (5) requires the knowledge of the electric potential ϕ . The closure is ensured by Maxwell’s equations, which however involve the *particle* distribution functions, while the gyrokinetic framework only treats the *gyro-center* distribution functions. The next section addresses this important issue.

Maxwell’s equations for fusion plasmas

The self-consistent treatment of plasma dynamics within the kinetic framework requires solving Maxwell’s equations, which link the electric, $\mathbf{E}$, and magnetic, $\mathbf{B}$, fields to the charge and current densities of particles. Maxwell-Gauss equation $\nabla^2 \phi = -\sum_s q_s n_s / \epsilon_0$ can be safely replaced by the quasi-neutrality condition $\sum_s q_s n_s = 0$ provided the electric potential, ϕ , develops on typical scales larger than the Debye length. This is actually the case for ion turbulence where the characteristic correlation length reaches a few ion gyro-radii. The approximation may however become marginal in cases where electron turbulence exhibits structures of a few electron gyro-radii. In controlled fusion devices, even when considering turbulence, it is often sufficient to replace $\mathbf{B}$ by the equilibrium guiding field, provided by the Grad-Shafranov equation (alternative formulation of the MHD—magneto-hydrodynamical—equilibrium). Conversely, MHD instabilities perturb the equilibrium magnetic field itself. In this case, Maxwell-Ampère equation, $\nabla \times \mathbf{B} = \mu_0 \sum_s \mathbf{j}_s$

(the displacement current $\partial_t E/c^2$ is negligible), provides the adequate response. Here, density and current simply relate to the particle distribution function through integrals over the velocity space $n_s = \int f_s d^3v$ and $j_s = q_s \int v f_s d^3v$.

The gyro-kinetic framework requires additional developments. Indeed, the challenge consists here in calculating n_s and j_s from the distribution function of the gyro-centers f_{Gs} , which is the only known kinetic quantity in this case. As a matter of fact, gyro-center f_{Gs} and particle f_s distribution functions are not equal a priori. Yet, the infinitesimal canonical transform from the particle phase space position $(\mathbf{x}, \mathbf{v})$ to the gyro-center one $(\mathbf{x}_G, \mathbf{v}_G)$ —permitted by the smallness of the ε parameter of the adiabatic theory—allows one to express f_{Gs} as a function of f_s . The transform makes use of the constraint, tied to the adiabatic limit, that the Hamiltonian of the gyro-centers should not depend on the fast gyro-phase φ_c . At first order in ε , the relationship reads as follows in the electrostatic case:

$$f_s(\mathbf{x}, \mathbf{v}, t) = f_{Gs}(\mathbf{x}_G, \mathbf{v}_G, t) + (q_s/B) [\phi(\mathbf{x}, t) - \langle \phi \rangle(\mathbf{x}_G, \mathbf{v}_G, t)] \partial f_{eq,s}(\mathbf{x}_G, \mathbf{v}_G, t) / \partial \mu_s \quad (6)$$

Notice that the gyro-average potential does not only depend on space but also on velocity coordinates, as expected since the gyro-radius ρ_s depends on the adiabatic invariant μ_s : $\rho_s = (2\mu_s/q_s\omega_{cs})^{1/2}$. At this point, closing the gyro-kinetic system in the long wavelength and electrostatic regime then simply requires solving the quasi-neutrality equation with n_s related to f_{Gs} in virtue of Eq. (6). In this case, further assuming $(k_\perp \rho_s)^2 \ll 1$ —usual although not always legitimate assumption—each density reads as follows:

$$n_s(\mathbf{x}, t) = \int J_s \cdot f_{Gs}(\mathbf{x}_G, \mathbf{v}_G, t) d^3v + \nabla_\perp \cdot [(m_s n_{eq,s} / q_s B^2) \nabla_\perp \phi(\mathbf{x}, t)]$$

The first term corresponds to the gyro-center density, with J_s the gyro-average operator. The second term corresponds to the polarization density, $n_{pol,s}$, which is negligible for electrons due to the proportionality to mass. A similar analysis can be performed in the electromagnetic case to compute the current density. In this case, in the same limit, the Maxwell-Ampère equation can be shown to take the following form:

$$-\nabla_\perp^2 A_{//}(\mathbf{x}, t) = \mu_0 \sum_s q_s \int [u_{G//s} J_s \cdot f_{Gs}(\mathbf{x}_G, \mathbf{v}_G, t) - (q_s/m_s) f_{eq,s}(\mathbf{x}, \mathbf{v}, t) J_s \cdot A_{//}(\mathbf{x}_G, \mathbf{v}_G, t) - v_{G//s} J_s \cdot f_{eq,s}(\mathbf{x}_G, \mathbf{v}_G, t)] d^3v$$

with $A_{//}$ the parallel component of the vector potential and $u_{G//s} = v_{G//s} + (q_s/m_s) A_{//}$ the canonical parallel velocity. In this formulation, the two first terms in the right hand side are very large as compared to the left hand side and almost cancel each other. This property is known as the “magnetic cancellation” issue. Computation strategies have been developed to deal with this difficulty.

Fluid and MHD equations

Fluid quantities are *moments* of the distribution function f_s , obtained by integrating f_s over the velocity space once weighted by k -order tensors of the velocity. The first three moments are the density $n_s(\mathbf{x}, t)$, the velocity $\mathbf{u}_s(\mathbf{x}, t)$ and the pressure tensor $P_s(\mathbf{x}, t)$. One also introduces the total heat flux $\mathbf{Q}_s(\mathbf{x}, t)$. They are defined as:

$$n_s = \int f_s d^3v; n_s \mathbf{u}_s = \int \mathbf{v} f_s d^3v; P_{s,ij} = \int m_s (v_i - u_i)(v_j - u_j) f_s d^3v; \mathbf{Q}_s = \int (m_s |\mathbf{v}|^2 / 2) \mathbf{v} f_s d^3v$$

The pressure tensor is often decomposed into a scalar pressure $p_s = \text{Tr}(P_s)/3$ (with Tr the trace of the tensor) plus a stress tensor π_s , such that $P_s = p_s I + \pi_s$ with I the unit tensor of rank 2 (other decompositions are sometimes useful, especially the one proposed by Chew-Goldberger-Low which accounts for pressure anisotropy: $P_{s,ij} = p_\perp s I + (p_{//s} - p_\perp s) b_i b_j + \Pi_{s,ij}$). Their time evolution is obtained by integrating the Vlasov Eq. (4)—including a collision operator in the right hand side if required—over the velocity space weighted by the corresponding k -order tensors. The three first equations lead to particle conservation, momentum balance and heat transport. In the case of short collisional mean free path, they are known as the Braginskii equations:

$$\partial_t n_s + \nabla \cdot (n_s \mathbf{u}_s) = 0 \quad (7)$$

$$n_s m_s (\partial_t \mathbf{u}_s + \mathbf{u}_s \cdot \nabla \mathbf{u}_s) + \nabla \cdot P_s = n_s q_s (\mathbf{E} + \mathbf{u}_s \times \mathbf{B}) + \mathbf{R}_s \quad (8)$$

$$\partial_t (3p_s/2 + m_s n_s |\mathbf{u}_s|^2 / 2) + \nabla \cdot \mathbf{Q}_s = q_s n_s \mathbf{u}_s \cdot \mathbf{E} + [\Delta \varepsilon]_{\text{coll.}}$$

where $\mathbf{R}_s$ is the drag force due to collisional interactions between species, and $[\Delta \varepsilon]_{\text{coll.}}$ Accounts for collisional energy transfer between species. At leading order, $\mathbf{R}_s$ reduces to the friction force $\mathbf{R}_s = -\sum_{s'} n_s m_s v_{ss'} (\mathbf{u}_s - \mathbf{u}_{s'})$. The conservation of the total energy (last equation), made of pressure and kinetic energy, can be rewritten by using mass and momentum conservations. Further neglecting the stress tensor $\pi_s \approx 0$ then leads to the following equation governing the dynamics of the pressure:

$$3/2 (\partial_t + \mathbf{u}_s \cdot \nabla) p_s + 5/2 p_s \nabla \cdot \mathbf{u}_s + \nabla \cdot \mathbf{q}_s = [\Delta \varepsilon]_{\text{coll.}} - \mathbf{u}_s \cdot \mathbf{R}_s \quad (9)$$

Here, $\mathbf{q}_s$ stands for the conductive heat flux: $\mathbf{q}_s = \int (m_s |\mathbf{v} - \mathbf{u}_s|^2 / 2) (\mathbf{v} - \mathbf{u}_s) f_s d^3v$.

The magneto-hydrodynamical (MHD) framework represents a peculiar sub-branch of the fluid approach, considering a one-fluid description of the plasma. It is particularly suited to study global equilibrium of magnetic configurations, and to explore the possible existence of magnetic instabilities. To this end, the mean flow, $\mathbf{U}$, is introduced: $\rho \mathbf{U} = \sum_s n_s m_s \mathbf{u}_s$, with $\rho = \sum_s n_s m_s$ the mass density (dominated by the ions). Similarly, $\mathbf{J} = \sum_s q_s n_s \mathbf{u}_s$ is the total current density. In the same spirit, the one-fluid pressure tensor $\bar{P}$ is defined as follows: $\sum_s n_s m_s \mathbf{u}_{s,i} \mathbf{u}_{s,j} = \rho \mathbf{U}_i \mathbf{U}_j + \sum_s n_s m_s (\mathbf{u}_{s,i} - \mathbf{U}_i)(\mathbf{u}_{s,j} - \mathbf{U}_j) + P_{ij}$. In the case of magnetized fusion

plasmas, $\bar{P}$ is diagonal and reduces to $P_{ij} = P\delta_{ij}$ in the isotropic case, with δ_{ij} the Kronecker symbol. In this framework, neglecting sub-dominant terms and considering the collisionless limit, continuity and momentum balance equations reduce to:

$$\partial_t \rho + \nabla \cdot (\rho \mathbf{U}) = 0 \quad (10)$$

$$\rho \, d\mathbf{U}/dt = \mathbf{J} \times \mathbf{B} - \nabla P \quad (11)$$

with $d/dt = (\partial_t + \mathbf{U} \cdot \nabla)$ the Lagrangian derivative. From Eq. (11), MHD equilibrium states that the Lorentz force balances the pressure gradient, and that the pressure is constant on magnetic surfaces. In the adiabatic limit, energy conservation takes the form of a state equation:

$$d(P/\rho^\Gamma)/dt = 0 \quad (12)$$

with $\Gamma = (N + 2)/N$ the adiabatic index (N = number of degrees of freedom), equal to 5/3 in the 3D case. The Ohm's law closes the system, complemented by Maxwell's equations. It derives from the dynamics of the current density and reads as follows in its simplest form:

$$\mathbf{E} + \mathbf{U} \times \mathbf{B} = \eta \mathbf{J} \quad (13)$$

where the Spitzer parallel resistivity η depends on the electron-ion collision frequency ν_{ei} : $\eta = m_e \nu_{ei} / (L_{11} n_e e^2)$, with L_{11} a correction coefficient of a few units accounting for electron-electron collisions ($L_{11} \sim 2$ for singly charged plasmas). Ideal MHD corresponds to the special case $\eta = 0$, while finite η values correspond to resistive MHD. The latter term introduces critical changes, especially allowing for changes in the magnetic topology leading to reconnection and magnetic islands. Several refinements with respect to these basic equations are considered in the literature, covering the broad spectrum of MHD physics, see (Lao, 2021).

Let us now address another important issue regarding the fluid approach. In the procedure leading to fluid equations, because Eq. (4) explicitly involves the velocity $\mathbf{v}$, it appears that any moment $M^{(k)}$ of order k is related to the $(k + 1)$ moment $M^{(k+1)}$, hence leading to an a priori infinite hierarchy of equations. A closure assumption is then required, consisting in replacing the dynamical equation of $M^{(k+1)}$ by some prescribed relation G between $M^{(k+1)}$ and the lower order moments: $M^{(k+1)} = G(M^{(1)}, \dots, M^{(k)})$. In regimes where collision frequencies are commensurable to, or even larger than, all other relevant frequencies, the distribution function can be assumed to remain close to a Maxwellian, which constitutes the kernel of collision operators. In this case, following the Chapman-Enskog procedure, which consists of a perturbative treatment at small Knudsen number (defined as the ratio of the collision mean free path to the macroscopic length scale of the system), Braginskii has derived in 1965 a set of closed fluid equations for collisional magnetized plasmas. Conversely, plasmas in the core of fusion devices are weakly collisional, the Knudsen number being much larger than unity. There, Braginskii equations are no longer valid. Actually, there is no universal closure in this case. In 1990, Hammett and Perkins (Hammett and Perkins, 1990) have proposed a procedure to account for kinetic effects in the closure. The idea consists in matching the kinetic and fluid linear response functions n_k/ϕ_k (with n_k and ϕ_k the Fourier components of density and electric potential fluctuations, respectively) in the kinetic limit, i.e. for phase velocities ω/k much smaller than the thermal velocity, $\omega/kv_T \ll 1$. The general result is that the Fourier component of the parallel heat flux scales like the sign of the parallel wave vector $k_{\parallel}$ times the temperature T_k . This corresponds to a non-local closure in real space, the local flux depending on distant values of the temperature. This procedure has been further extended and applied to several fluid models, exhibiting some success particularly in the astrophysical context. Yet, several limitations have to be mentioned: it remains linear, hence questioning its validity in the nonlinear regime; it is model dependent, and can lead to closures which may turn out to be complicated to implement numerically; last but not least, it does not prevent over damping of large scale flows, which efficiently contribute to turbulence saturation in tokamak plasmas.

Fluid drifts

The fluid equations derived in the previous section do not make use of the adiabatic limit which holds for hot and magnetized fusion plasmas. In this adiabatic framework, it will be shown that the components of the fluid velocity transverse to the magnetic field can be computed explicitly order by order with respect to the small parameter $\varepsilon = \omega/\omega_{cs} \approx \rho_{cs}/R \ll 1$, with ω the largest relevant frequency of the considered problem: $\mathbf{u}_{s\perp} = \mathbf{u}_{s\perp}^{(1)} + \mathbf{u}_{s\perp}^{(2)} + \dots$, with the notation $|\mathbf{u}_{s\perp}^{(j)}|/v_{Ts} \sim O(\varepsilon^j)$.

Let us consider the transverse components of the momentum conservation equation, Eq. (8). The leading order terms are the gradient of the scalar pressure and the Coulomb and Lorentz forces. Indeed, the Lagrangian derivative term is of higher order, scaling like ε times the Lorentz force, as a consequence of the adiabatic hypothesis. Also, the anisotropic and off-diagonal components of the pressure tensor contribute to a small correction of the scalar pressure, of order ε . Finally, the friction force can be neglected in these weakly collisional plasmas. Then, cross-multiplying this three-terms balance equation by $\mathbf{B}$ provides the expression of the leading order term of the transverse velocity:

$$\mathbf{u}_{s\perp}^{(1)} = (\mathbf{E} \times \mathbf{B})/B^2 + (\mathbf{B} \times \nabla p_s)/q_s n_s B^2 \quad (14)$$

The first term is the electric drift $\mathbf{u}_E$, which has also been encountered when deriving the transverse drifts of the gyro-center. Its gyro-fluid expression consists in replacing the electric field $\mathbf{E}$ by its gyro-average over a thermal gyro-radius $\langle \mathbf{E} \rangle_T$. In this case, the electric drift depends—weakly—on the species. The fluctuations of this velocity drift govern turbulent transport across the magnetic surfaces. The second term corresponds to the diamagnetic drift, often denoted $\mathbf{u}_s^*$. It is the same order of magnitude, but opposite in

direction, for electrons and ions. As such, it carries a non-vanishing transverse current, actually the one which ensures global MHD equilibrium through the Lorentz force. It results from the effective imbalance of particle gyro-motions in one direction and the other in the presence of a finite pressure gradient (cf. Fig. 2C). Interestingly, note that the divergence of the electric drift—in the electrostatic limit where $\mathbf{E} = -\nabla\phi$ —and of the diamagnetic current are vanishing in the case of an homogeneous magnetic field. Conversely, they scale like $\nabla \times (\mathbf{B}/B^2)$ in the inhomogeneous case, which is small because of the large gradient length R of the guiding magnetic field.

Deriving the second order fluid drift $\mathbf{u}_s^{(2)}$ is more complex. Indeed, the next order expression of the transverse momentum conservation involves the following terms, assuming parallel advection can be neglected: $[\partial_t + \mathbf{u}_s^{(1)} \cdot \nabla] \mathbf{u}_s^{(1)} + \nabla \cdot \pi_{s\perp} = q_s n_s \mathbf{u}_s^{(2)} \times \mathbf{B}$. In particular, it requires the evaluation of the divergence of the anisotropic and off-diagonal terms of the pressure tensor—the stress tensor π_s —which derives from kinetic effects. It can be shown, at leading order, that the Lagrangian derivative of the diamagnetic flow $[\partial_t + \mathbf{u}_s^{(1)} \cdot \nabla] \mathbf{u}_s^*$ balances the divergence of the stress tensor $\nabla \cdot \pi_{s\perp}$ up to a gradient term $\nabla_\perp \chi_s$. Here, the scalar χ_s turns out to be smaller than the pressure in the ratio $\chi_s/p_s \sim \omega/\omega_{cs} \ll 1$, so that it is often ignored. Then again, cross-multiplying by $\mathbf{B}$ yields the expression of $\mathbf{u}_s^{(2)}$, called the extended polarization drift $\mathbf{u}_{\text{pol},s}$. In the relevant electrostatic limit, it reads as follows

$$\mathbf{u}_{\text{pol},s} = - (m_s/q_s B^2) [\partial_t + (\mathbf{u}_E + \mathbf{u}_s^*) \cdot \nabla] \nabla_\perp \phi \quad (15)$$

It can be verified that it is $\epsilon \sim \omega/\omega_{cs}$ smaller than the electric drift, as expected. Because it is proportional to mass, it is negligible for electrons. The divergence of the polarization current is often commensurable to that of the diamagnetic current, so that both have to be accounted for in the charge conservation equation.

Let us now address the important issue of the consistency between kinetic and fluid descriptions within the adiabatic framework. We shall here restrict ourselves to the first order of the development in ϵ . At this order, particle and fluid drifts exhibit the same electric drift, but depart from each other regarding the other component. The issue then reduces to comparing the transverse currents originating from the particle motion on the one hand and from the fluid description on the other hand. The fluid one simply derives from the diamagnetic drift: $\mathbf{j}_s^{(\text{fluid})} = (\mathbf{B} \times \nabla p_s)/B^2$. Regarding the kinetic current, it is made of two contributions: the one arising from the transverse drift of the gyro-centers $\mathbf{j}_{ds} = \int q_s \mathbf{v}_{ds} f_{Ms} d^3v$, and the magnetization current due to the cyclotron motion $\mathbf{j}_{s,\text{magn}} = \nabla \times \mathbf{M}_s$, with $\mathbf{M}_s = -(\int \mu_s f_{Ms} d^3v) \mathbf{b}$ the magnetization. The integrals are performed over the entire velocity space, the volume element being $d^3v = (2\pi B/m_s) dv_{G//s} d\mu_s$. Consistently with the fluid analysis which we have considered here, we take an isotropic and centered Maxwellian distribution function for the particles (the calculation can be easily extended to the anisotropic case characterized by different parallel and perpendicular temperatures), $f_{Ms} = n_s/(2\pi v_{Ts}/m_s)^{3/2} \exp[-(m_s v_{G//s}^2/2 + \mu_s B)/2T_s]$. This yields: $\mathbf{j}_{ds} = 2p_s \mathbf{B} \times \nabla B/B^3 + p_s (\nabla \times \mathbf{B})_\perp/B^2$ and $\mathbf{j}_{s,\text{magn}} = (\mathbf{B} \times \nabla p_s)/B^2 - 2p_s \mathbf{B} \times \nabla B/B^3 - p_s (\nabla \times \mathbf{B})_\perp/B^2$, so that one effectively recovers $\mathbf{j}_s^{(\text{fluid})} = \mathbf{j}_s^{(\text{kinetic})} = \mathbf{j}_{ds} + \mathbf{j}_{s,\text{magn}}$, as one should. Also, consistently with the physical picture of the diamagnetic current, one finds that it is entirely contained within the cyclotron motion. Finally, notice that the magnetization current is divergenceless, so that it does not contribute to the charge conservation equation.

Collisions and neoclassical theory

Coulomb collisions are rare in the core of fusion plasmas, the collisional mean free path reaching typically one hundred toroidal turns along the particle trajectory. The resulting cross-field transport is therefore weak, several orders of magnitude less than turbulent transport in most confinement regimes in tokamaks. Yet, collision physics cannot be ignored. On the most fundamental ground, collisions enforce the Boltzmann H-theorem and relaxation of distribution functions towards Maxwellians. In addition, in fusion devices, collisional transport can become commensurable to turbulent transport in improved confinement regimes or in non-axisymmetric configurations such as stellarators. It may even become dominant for the transport of heavy impurities from the edge—where they are emitted due to plasma-wall interactions—to the core—where they degrade the performance through radiation and fuel dilution. Also, they often govern the level of large scale plasma flows, which play a critical role in turbulence saturation. Finally, they are responsible for the inward particle pinch and toroidal plasma current, both essential to fusion performance.

Expression and order of magnitude of collision frequencies

Coulomb interaction is long distance, so that particles interact with each other continuously. At distances larger than the Debye length, these interactions are mediated by the mean electromagnetic field, governed by Maxwell's equations. At smaller distances, they are treated as binary collision processes. The mean distance between particles, λ_D , being several orders of magnitude larger than the minimal distance of interaction, λ_L , most of the collisions are grazing. Their large number within a Debye sphere—the number of particles being of the order of one billion—then allows for a statistical treatment. The Coulomb collision frequency, $\nu_{ss'}$ of particle species s colliding on particle species s' is defined as the inverse of the time needed for the velocity vector of particles s to be deflected by about 90 degrees. It results from a Markovian process involving a large number of interactions. We need first to characterize one single interaction so as to derive the expression of $\nu_{ss'}$.

Let s and s' be two interacting charged particles, with s' assumed at rest. Let b be impact parameter, the distance between s' and the direction of the trajectory of particle s with velocity $\mathbf{v}_s$ at $t \rightarrow -\infty$. As derived by Rutherford, at $t \rightarrow +\infty$, the trajectory of s is

deflected by the angle θ such that $\tan(\theta/2) = \lambda_L/2b \ll 1$, where we recall that $\lambda_L = q_s q_{s'}/2\pi\epsilon_0 m_s v_s^2$. θ also measures the relative variation of the velocity projected on the trajectory at $t \rightarrow -\infty$: $\theta \approx \delta v_s/v_s$.

In the case where s interacts with a lot of particles s' , the average deflection $\langle \delta v_s^2 \rangle$ per time τ then reads as follows: $\langle \delta v_s^2 \rangle / \tau v_s^2 = \int \theta^2 n_{s'} dV / \tau$, with $\int n_{s'} dV$ the total number of interacting s' particles during the time interval τ . The volume element is then $dV = 2\pi b db v_s \tau$. The integral diverges in both limits, $b \rightarrow 0$ and $b \rightarrow +\infty$. It is typically to be performed between $b_{\min} = \lambda_L$ —limit of grazing collisions—and $b_{\max} = \lambda_D$ —limit of charge screening and interaction through the mean fields. Further imposing $\langle \delta v_s^2 \rangle / v_s^2 = 1$ and accounting for the fact that s' particles are not at rest a priori provides the expression of $v_{ss'}$:

$$v_{ss'} = \text{Ln}(\Lambda) (\sqrt{(2\pi)/3}) q_s^2 q_{s'}^2 n_{s'} (1/m_s + 1/m_{s'}) / 4(\pi\epsilon_0)^2 m_s (v_{Ts}^2 + v_{Ts'}^2)^{3/2} \quad (16)$$

With $\text{Ln}(\Lambda) = \text{Ln}(\lambda_D/\lambda_L) \approx 20$ defined as the Coulomb logarithm. Notice that $v_{ss'}$ scales typically like $n/T^{3/2}$. Also, it is all the larger since mass is small. Denoting $K = \text{Ln}(\Lambda) (\sqrt{(2\pi)/3}) e^4 n_e / 4(\pi\epsilon_0)^2$, the expressions of typical collision frequencies between electrons and ions of charge Z read as follows:

$$v_{ee} = K/(2m_e)^{1/2} T_e^{3/2}; \quad v_{ei} = Z\sqrt{2} v_{ee}; \quad v_{ii} = Z^3 (m_e/m_i)^{1/2} v_{ee}; \quad v_{ie} = Z\sqrt{2} (m_e/m_i) v_{ee}$$

Here, for the sake of simplicity, quasi-neutrality $Zn_i = n_e$ has been used and equal ion and electron temperatures have been assumed. In the core of ITER plasmas, v_{ei} is expected to be of order 10^4 s^{-1} . For deuterium ions, $(m_e/m_i)^{1/2} \approx 1/60$, so that v_{ie} is negligible by comparison. Finally notice that $m_e v_{ei} = m_i v_{ie}$ so that the friction force exerted by ions on electrons is exactly opposed to that exerted by electrons on ions, consistently with the action-reaction principle.

Basics of neoclassical transport

Collisions generate heat transport across magnetic surfaces in controlled fusion devices. Consistently with the random walk estimate of Brownian motion, they lead to diffusive transport with coefficient $D_{\text{neo}} = \langle \Delta r^2 \rangle / \tau$, where Δr is the random displacement and τ the characteristic time between collisions. Neoclassical theory refers to the theory of Coulomb binary collisions in the toroidal magnetic geometry of controlled fusion devices, where their effects are amplified by particle trajectories which explore the whole configuration. The precise derivation of neoclassical transport coefficients in the various collisional regimes is cumbersome. Yet, the critical dependencies can be captured through rather simple arguments. The key parameter is the collisionality ν^* , ratio of the effective detrapping frequency, ν_{eff} , to the bounce frequency, ω_b , for thermal particles: $\nu^* = \nu_{\text{eff}}/\omega_b = e^{-3/2} v_c qR/v_T$, with v_c the collision frequency. Here, the expression of ν_{eff} derives from the following analysis. Consistently with their Markovian character, elastic collisions lead to diffusion in velocity space with coefficient $D_v = \langle \Delta v^2 \rangle \nu_c \approx v_c v_T^2$. According to the section “**Passing and trapped particles**”, trapped particles become passing when the ratio $v_{\parallel}/v_{\perp}$ becomes larger than $(2\epsilon)^{1/2}$. The evolution of their parallel velocity is governed by $\langle \Delta v_{\parallel}^2 \rangle = D_v t$. Hence, $1/\nu_{\text{eff}}$ corresponds to the time required for $\langle \Delta v_{\parallel}^2 \rangle$ to be of the order of $2\epsilon v_{\perp}^2$. Considering thermal particles $v_{\perp} = v_T$, this condition then yields $\nu_{\text{eff}} \approx v_c/2\epsilon$.

In the low collisionality (banana) regime $\nu^* \ll 1$, trapped particles bounce back and forth several times before being detrapped by collisions. They bring the main contribution to $D_{\text{neo}} = D_b$. Their characteristic random displacement is $\Delta r = \delta_b$, and the characteristic banana lifetime is $\tau = 1/\nu_{\text{eff}}$. Then, accounting for the trapped particle fraction, f_t , one finally obtains: $D_b = f_t \delta_b^2 \nu_{\text{eff}} = q^2 \rho_c^2 v_c / \epsilon^{3/2}$, which is $q^2/\epsilon^{3/2}$ times larger than the classical diffusion coefficient in straight field line configurations.

In the intermediate (plateau) regime $\nu^* \approx 1$, most of thermal particles are passing—trapped particles being detrapped before exploring their full orbit—and collisionless. The characteristic displacement is then $\Delta r = q\rho_c$ and the characteristic time $\tau = qR/v_T$, so that $D_p = q\rho_c^2 v_T/R$. This does not depend on the collision frequency, so that D_{neo} exhibits a plateau when plotted with respect to ν^* . Also notice that it is equal to D_b at the banana-plateau boundary, $\nu^* = 1$.

The high collisionality regime is named after its two main discoverers, Pfirsch and Schlüter. There, for $\nu^* \gg 1/\epsilon^{3/2}$, particles experience collisions before completing the full connection length path along the magnetic field. Their parallel motion is diffusive with the characteristic diffusion coefficient $D_{\parallel} = v_T^2/\nu_c$. This determines the characteristic time scale over the connection length: $\tau_{\parallel} = q^2 R^2/D_{\parallel}$. The characteristic displacement transverse to the magnetic surfaces is still governed by the magnetic drifts—curvature and $\text{grad}(B)$ —which scale like $v_d \approx v_T \rho_c/R$, so that $\Delta r = v_d \tau_{\parallel}$. In the end, the Pfirsch-Schlüter diffusion coefficient reads as follows: $D_{\text{PS}} = q^2 \rho_c^2 \nu_c$. Again, both diffusion coefficients D_p and D_{PS} smoothly match at the plateau-Pfirsch-Schlüter boundary at $\nu^* = 1/\epsilon^{3/2}$.

Given the expected profiles of density, temperature and safety factor in ITER plasmas, electrons and main ion species are expected to be in the banana regime ($\nu^* \ll 1$) in most of the confined region—except in the very core where the trapped fraction drops to zero. Conversely, many impurities will be in the plateau or even the Pfirsch-Schlüter regime, the latter being expected in the edge region for heavy impurities.

Neoclassical theory within the fluid framework

The theory of neoclassical transport requires a kinetic treatment which is beyond the scope of the present introduction. Yet, the main results can be recovered within the fluid framework provided neoclassical effects are implemented via a parallel force which will be detailed below (Garbet, 2020). It is stressed that this calculation provides an illustration of the physical processes at work, but should not be used for quantitative estimates. All calculations in this section are performed in the limit of large aspect ratio

axisymmetric tokamaks, $\epsilon \ll 1$, and the cylindrical approximation, $q = \epsilon B_\phi / B_\theta \approx \epsilon B / B_\theta$. Also, all quantities are assumed to be independent of the toroidal angle. The non-axisymmetric case will be addressed in the next section.

Let us consider the momentum balance equation at equilibrium $d/dt = 0$ (Eq. (8), Section “The three motion invariants”): $\nabla p_s + \nabla : \bar{\pi}_s = n_s q_s (\mathbf{E} + \mathbf{u}_s \times \mathbf{B}) + \mathbf{R}_s$, with $\bar{\pi}_s$ the stress tensor and $\mathbf{R}_s$ the friction force. Neoclassical kinetic results provide the explicit expression of the parallel projection of $\nabla : \bar{\pi}_s$, which defines the opposite of the neoclassical parallel force $F_{//s}$:

$$F_{//s} = -\mathbf{b} \cdot (\nabla : \bar{\pi}_s) = -n_s m_s \mu_s (u_{\theta s} - k_s \nabla_r T_s / q_s B) \quad (17)$$

Where the coefficients μ_s and k_s , calculated within the kinetic framework, depend on the collisionality regime. Conversely, axisymmetry imposes $\nabla \phi \cdot (\nabla : \bar{\pi}_s) = 0$. Then, the radial, parallel and (parallel minus toroidal) projections of the equilibrium momentum balance yield the following set of equations, assuming the pressure is constant on magnetic surfaces (as imposed by the MHD equilibrium Eq. (11)):

$$\nabla_r p_s / n_s q_s = E_r + u_{\theta s} B - u_{//s} B_\theta \quad (18)$$

$$F_{//s} + n_s q_s E_{\text{ind}} - \sum_{s'} n_s m_s v_{ss'} (u_{//s} - u_{//s'}) = 0 \quad (19)$$

$$F_{//s} - q_s \Gamma_{rs} B_\theta = 0 \quad (20)$$

Here, $\Gamma_{rs} = n_s u_{rs}$ is the radial particle flux and E_{ind} the inductive field used to generate the poloidal magnetic field B_θ . Consistently with the large aspect ratio limit, the toroidal and parallel velocities have been taken equal.

The friction term in Eq. (19) is usually dominant for ion species, so that their parallel/toroidal velocities are approximately the same. We will assume it is the case in the following. Notice however that this approximation may break down when density and temperature gradients are large.

Summing Eq. (19) over all species shows that $\sum_s F_{//s} = 0$ (as a result of quasi-neutrality $\sum_s n_s q_s = 0$ and the action-reaction principle $\sum_{ss'} n_s m_s v_{ss'} (u_{//s} - u_{//s'}) = 0$: collisions do not inject net momentum), so that, summing now Eq. (20), neoclassical transport appears to be automatically ambipolar: $\sum_s q_s \Gamma_{rs} = 0$. This means that the radial electric field cannot be calculated from these equations. Breaking the axisymmetry hypothesis would alleviate the degeneracy.

Eq. (20) shows that poloidal velocities need to be calculated to get an expression of particle fluxes. The key step is provided by the relation $\sum_s F_{//s} = 0$. To further carry on the calculations, we will consider the case where several species are present, namely electrons, deuterium ions and an impurity of charge Z . In the banana regime, $\mu_e = 1.46 v_{eD} (0.53 + Z_{\text{eff}}) q / \epsilon^{1/2}$ and $k_e = (0.62 + 1.5 Z_{\text{eff}}) / (0.53 + Z_{\text{eff}})$, with $Z_{\text{eff}} = \sum_i n_i Z_i^2 / n_e$ the effective charge number. The coefficients for deuterium are deduced from those for electrons by replacing Z_{eff} by the dilution parameter $\alpha = n_Z Z^2 / n_e$ and v_{eD} by $v_{DD} \sqrt{2}$. In the case of a dilute impurity $\alpha \ll 1$, one finds $\mu_D = 1.10 v_{DD} q / \epsilon^{1/2}$ and $k_D \approx 1.17$. In the plateau regime, the coefficients are $\mu_s = 1.25 \epsilon v_{Ts} / R_0$ and $k_s = -0.5$. It appears that $F_{//e}$ is negligible as compared to $F_{//D}$, in the typical ratio $(m_e / m_D)^{1/2}$. Also, $F_{//Z}$ can be neglected if the impurity concentration is low ($\alpha \ll 1$) or if it is in the Pfirsch-Schlüter regime where μ_Z is very low. In these most relevant cases, the sum reduces to $F_{//D} = 0$, i.e.:

$$u_{\theta D} = k_D \nabla_r T_D / e B \quad (21)$$

The ion poloidal rotation is low due to friction on trapped particles which do not rotate poloidally by definition. In the frame of these approximations, Eq. (20) cannot be used to calculate Γ_{rD} . Instead, the ambipolarity constraint is used once Γ_{re} and Γ_{rZ} have been calculated.

Subtracting Eq. (18) for deuterium and impurity eliminates E_r and yields $u_{\theta Z}$:

$$u_{\theta Z} = (T_D / e B) [\nabla_r n_Z / Z n_Z - \nabla_r n_D / n_D + (k_D - 1 + 1/Z) \nabla_r T_D / T_D]$$

Here, equal temperatures and parallel velocities have been assumed. Note that, for large charge number, the impurity poloidal velocity can have the opposite sign to the deuterium poloidal velocity. The impurity flux then simply results from Eq. (20) and the above expression for $u_{\theta Z}$, valid in banana and plateau regimes:

$$\Gamma_{rZ} = -n_Z D_Z [\nabla_r n_Z / n_Z - Z \nabla_r n_D / n_D - H_Z \nabla_r T_D / T_D]$$

With $D_Z = (q / \epsilon) \mu_Z m_Z T_D / (Z e B)^2$ the impurity diffusion coefficient and $H_Z = [1 - k_D + (k_Z - 1) / Z]$ the screening factor. The first term in the parenthesis accounts for diffusion, the second one leads to impurity peaking and the last is thermo-diffusion. It can lead to thermal screening—i.e. the expulsion of impurities from the core—if H_Z is negative ($\nabla_r T_D < 0$ due to central heating). In the limit of large Z , $H_Z = 3/2$ if deuterium is in the plateau regime while H_Z is marginally negative (close to zero when accounting for finite ϵ corrections) if it is in the banana regime. If deuterium and impurity ions are in the same collisionality regime, then their diffusion coefficients are the same: $D_Z / D_D \sim (m_Z / Z^2 m_D) v_{ZD} / v_{DD} \sim 1$ since $v_{ZD} / v_{DD} \sim Z^2 m_D / m_Z$ (v_{ZD} dominates over v_{ZZ} at low impurity concentration). However, since $v_Z^* / v_D^* \sim Z^2 (m_D / m_Z)^{1/2}$, high Z impurities are often in the plateau or Pfirsch-Schlüter regime even if deuterium is in the banana regime. If the impurity is in the plateau regime, one then finds $D_Z / D_D \sim 1 / v_Z^* \ll 1$. This is why turbulence is often the dominant transport channel for impurity diffusion. For impurities in the Pfirsch-Schlüter regime, another expression should be used for their radial flux:

$$\Gamma_{iZ}^{(PS)} = -n_Z D_Z^{(PS)} \left[\nabla_r n_Z / n_Z - Z \nabla_r n_D / n_D - \left(Z H_Z^{(PS)} / K_Z \right) \nabla_r T_D / T_D \right]$$

With the new expressions: $D_Z^{(PS)} = v_{ZD} m_Z T_D (q / ZeB)^2$, $H_Z^{(PS)} = -0.5 + (0.29 + 0.68\alpha) / (0.59 + \alpha + 1.34/g^2)$, $K_Z = 1 - 0.52\alpha / (0.59 + \alpha + 1.34/g^2)$ and $g = v_D * \epsilon^{3/2} / \sqrt{2}$. If the main ion is in the banana or plateau regime, then $g \ll 1$ and $K_Z \approx 1$ and $H_Z^{(PS)} \approx -1/2$ so that impurities are screened in the Pfirsch-Schlüter regime.

Subtracting Eq. (18) for deuterium and electrons relates $u_{\theta e}$ to $u_{\theta D}$ and the parallel current $j_{||} = -ne(u_{||e} - u_{||D})$. The latter can be eliminated by using the Ohm's law Eq. (19) for electrons, hence leading to the following approximate expression (with the assumption $(\epsilon/q)(\mu_e/v_{eD}) \ll 1$ valid for $\epsilon \ll 1$):

$$u_{\theta e} = -(1/eB) [(T_D + T_e) \nabla_r n_e / n_e + \nabla_r T_e / T_e + (1 - k_D) \nabla_r T_D / T_D] - (\epsilon/q) e E_{ind} / (m_e v_{eD})$$

The electron radial flux and parallel current then read as follows in the banana regime:

$$\Gamma_{re} = -n_e D_e [(1 + T_D / T_e) \nabla_r n_e / n_e + (1 - k_e) \nabla_r T_e / T_e + (1 - k_D) \nabla_r T_D / T_e] - (C_e \epsilon^{1/2} / B_0) n_e E_{ind}$$

$$j_{||} = - (C_e \epsilon^{1/2} / B_0) [(T_D + T_e) \nabla_r n_e + (1 - k_e) n_e \nabla_r T_e + (1 - k_D) n_e \nabla_r T_D] + \sigma_{neo} E_{ind}$$

With $D_e = C_e v_{eD} m_e T_e (q/eB)^2 / \epsilon^{3/2}$, $C_e = 1.46(0.53 + Z_{eff})$ and $\sigma_{neo} = n_e e^2 / m_e v_{eD}$ the neoclassical conductivity. The term proportional to the inductive field in Γ_{re} is known as the Ware pinch.

Bootstrap current and neoclassical resistivity

The so-called 'bootstrap current' is the term proportional to density and temperature gradients (to the pressure gradient only in the limit of unit aspect ratio $\epsilon = 1$) in the expression for $j_{||}$. It is the Onsager symmetric of the Ware pinch. It arises from the fact that, when electrons get detrapped, they carry a finite amount of parallel momentum due to the difference of density and temperature on the inner and outer sides of their banana orbit. The bootstrap current plays a critical role in tokamaks, in particular in the perspective of a steady-state reactor. Indeed, in regions with non-vanishing density and temperature gradients, it can substantially contribute to the total current, hence decisively contributing to the magnetic equilibrium of the configuration. As such, it constitutes one of the most important outputs of neoclassical physics.

The bootstrap current adds to the inductive current, the last term in the expression of $j_{||}$. It is to be noted that neoclassical effects lead to an increase of the resistivity, η_{neo} , as compared to the Spitzer formula (cf. Eq. 13), which is valid for a straight magnetic field. Again, it results from the fact that trapped electrons do not carry any current. A more careful derivation of the neoclassical conductivity $\sigma_{neo} = 1/\eta_{neo}$ then yields $\sigma_{neo} \sim \sigma(1 - \epsilon^{1/2})^2$ with $\sigma = 1/\eta$ the Spitzer conductivity. Due to the increase of collision frequency towards the plasma edge, which gets lighter and cooler, resistivity also increases at the edge. This effect, combined with the large pressure gradient at the edge, leads to a bootstrap current profile which peaks away from the magnetic axis, as evident in Fig. 4.

Some considerations on neoclassical transport in non-axisymmetric systems

In tokamak magnetic configurations, axisymmetry (toroidal invariance) provides the third invariant—the toroidal canonical momentum P_ϕ —which ensures particle confinement. Helical configurations, such as stellarators, lack such symmetry and hence any third invariant—the same holds in tokamaks if the ripple due to the discreteness of the toroidal field coils is large. De facto, particle trajectories may then explore a large volume, and even hit the wall, unless the magnetic field is optimized to prevent this. Neoclassical transport in stellarators turns out to be much larger than that in tokamaks in the low collisionality, large mean free path case which prevails in the core of hot fusion plasmas (cf. for instance the review articles (Helander, 2014; Boozer, 2015) on non-axisymmetric magnetic confinement). The present short section cannot do justice to the vast and rich literature on this important and difficult topic. It mainly aims at highlighting major results and routes towards configuration optimization.

In helical configurations, the magnetic field strength may typically exhibit the following structure:

$$B \approx B_0 [1 - \epsilon_1 \cos\theta - \epsilon_2 \cos(m\theta - n\phi)]$$

Where the ϵ_1 term is due to toroidicity while the ϵ_2 term accounts for the dominant helical structure, with (m, n) integer constants. In the case of tokamak ripple, $m = 0$ and n is the number of toroidal coils. Along field lines, B then exhibits the usual sinusoidal shape plus corrugations which, if large enough—and this is usually the case in stellarators—can lead to local trapping of the particles and superbanana orbits. If superbanana orbits remain collisionless, then the transport coefficient can be estimated the same way as for the banana regime in tokamaks, with the banana width replaced by the typical radial width δ_{sb} of the superbanana orbits and ν_{eff} being the effective scattering frequency of particle detrapping in these local wells: $D = \delta_{sb}^2 \nu_{eff}$. In this situation, neoclassical transport can become very large, much larger than banana transport in tokamaks. The stringent assumption of collisionless superbanana orbits is however hardly fulfilled. Conversely, if the orbits are interrupted by collisions, δ_{sb} should be replaced by the radial excursion of the order (v_{ds}/v_{eff}) , with $v_{ds} \sim T_s/(q_s B R)$ the essentially vertical magnetic drift. It readily appears that, in this case, $D \sim (v_{ds}/v_{eff})^2 \nu_{eff} = v_{ds}^2 / \nu_{eff}$ is inversely proportional to collisionality. This so-called $1/\nu$ regime, which does not exist in tokamaks, is orders of magnitudes larger than the banana regime. Also, the corresponding

Fig. 4 Typical expected profiles of density, temperature, safety factor and bootstrap current in ITER plasmas.

Fig. 5 Frenet frame attached to a 3-dimensional curve.

heat flux exhibits a very unfavorable scaling with temperature, like $T^{9/2}$, as compared to $T^{1/2}$ in the low collisionality regime of tokamak plasmas.

Considerable effort has been invested to develop clever optimized configurations aiming at reduced neoclassical transport in non-axisymmetric devices. The interested reader can refer to the pioneering successful efforts in this direction (Nührenberg and Zille, 1988; Grieger et al., 1992) and to more recent developments (Mynick, 2006; Gates et al., 2017). Quasi-helical or quasi-symmetric configurations target magnetic field strength exhibiting a single helicity state in appropriate coordinates. It can be shown to result in a new invariant which replaces P_ϕ . Such a state cannot be perfectly achieved in toroidal configurations, hence *quasi*. An alternative consists in making the magnetic field quasi-omnigenous, i.e. such that the net radial excursion due to the magnetic drift $\mathbf{v}_{ds}$ almost vanishes when bounce averaged over particle trajectories. Numerical simulations have already shown that orders of magnitudes could be gained regarding neoclassical transport in optimized configurations. Experiments are ongoing, most notably in the Wendelstein7-X stellarator (Yamada, 2021).

Introduction

Obviously, the goal of magnetic confinement is to devise a magnetic field structure that is able to retain a hot fusion plasma as well as possible. Most notably, the product of the central plasma pressure and the energy confinement time has to exceed the limit provided by the Lawson criterion to achieve a burning (i.e., self-heated) plasma, as explained elsewhere in this Encyclopedia.

In the early days of fusion research, many different concepts have been tested, but two emerged as the most promising candidates, the tokamak and the stellarator. Both of these types of devices create magnetic field lines which form nested toroidal surfaces, and one might expect that such a setup is perfect for confinement, given that the charged plasma particles follow those field lines and should thus remain on those surfaces.

Upon closer inspection, one notices that this consideration is not quite correct. Due to the fact that magnetic field lines in such toroidal devices are strongly inhomogeneous, varying spatially in both strength and direction, the plasma particles temporarily drift away from their flux surfaces, and collisions then lead to radial displacements of their drift centers, inducing a loss of heat and particles. Such transport processes are called “neoclassical,” and the corresponding physics basis has been described elsewhere in this Encyclopedia.

While quantitative estimates suggest that neoclassical losses are tolerable in practice, there exists yet another transport process which is much more restrictive. As it turns out, heat and particle transport across magnetic fields (at least in tokamak plasmas) is usually dominated by turbulence-driven processes, typically exceeding the predictions of neoclassical transport by about one order of magnitude or more. This is not surprising, given that turbulence is known to be an excellent agent of spatial transport in a wide range of physical systems. Consequently, it has become one of the central goals of fusion theory to help understand, predict, and control turbulent transport in fusion devices.

In the following, we will first describe the character, origin, and consequences of turbulent fluctuations which are observed in fusion experiments. Then we will discuss the fundamental nature of plasma microturbulence, including its relation to turbulence in fluids and astrophysical systems. Subsequently, we will provide a brief introduction to gyrokinetics, which has become the default physical model for theoretical and computational studies of turbulence in fusion plasmas. Finally, we will give two prime examples of combined experimental and theoretical efforts to control turbulent transport. We will close with some conclusions and an outlook.

Small-scale fluctuations in fusion plasmas

Both tokamaks and stellarators usually exhibit nested toroidal flux surfaces, spanned by magnetic field lines, in their core region (the situation is more complex in the edge region and will not be discussed here much further). Due to the fact that particle and heat

transport processes parallel to the field lines are very fast compared to their perpendicular counterparts in this region of the plasma, the average densities and temperatures of each particle species tends to be constant on each such surface. However, one observes small fluctuations, of the order of a percent or less. At the same time, there are also exist small fluctuations of other plasma quantities like the average parallel velocity or the parallel heat flux of each plasma species as well as of the self-generated electric and magnetic fields. These fluctuations are a result of plasma turbulence caused by the enormous spatial variations in the plasma density and temperature across flux surfaces, and the induced turbulent transport in the radial direction turns out to determine the energy confinement time—one of the key figures of merit of any magnetic confinement fusion device—as well as the confinement of plasma particles and impurities.

Characterization of the observed fluctuations

Via careful experimental studies, it became possible to characterize the observed fluctuations. Perpendicular to the background magnetic field, they tend to have a typical extent of several millimeters to a few centimeters, while in the parallel direction, they can be stretched out over tens of meters. This very anisotropic structure is due to the fact that plasma particles can move more or less freely along magnetic field lines, but drift only very slowly across the field lines.

The parallel extent is related to the so-called connection length, $L_c = 2\pi qR$, which is the length of a given magnetic field line while it completes a full poloidal turn. Here, R is the major radius of the toroidal device—and q is the safety factor associated with a given flux surface, i.e., the number of toroidal turns per poloidal turn for a field line on that surface. For an experiment like ASDEX Upgrade at Garching, Germany, we have $R \sim 1.65$ m and $q \sim 2$, which yields $L_c \sim 20$ m.

Meanwhile, the perpendicular extent of the fluctuations corresponds to several ion gyroradii. Noting that the gyroradius of thermal ions is given by $\rho_i = v_{ti}/\Omega_i$ where $v_{ti} = (k_B T_i/m_i)$ is the ion thermal velocity and $\Omega_i = (q_i B)/(m_i c)$ is the ion gyrofrequency, we have $\rho_i [\text{mm}] \sim 3.2 \sqrt{T_i [\text{keV}]/B [\text{T}]}$ for protons. (Here, k_B is Boltzmann's constant, T_i is the ion temperature, m_i is the ion mass, q_i is the ion charge, B is the magnetic field strength, and c is the speed of light.) In the case of ASDEX Upgrade, for $T_i [\text{keV}] = 4$ and $B [\text{T}] = 2.5$, one obtains a thermal proton gyroradius of about 3.6 mm. Measurements suggest that the perpendicular correlation lengths of the fluctuations are in the range of up to about $10 \rho_i$, i.e., a few cm. We are thus dealing with a parallel/perpendicular aspect ratio of the fluctuations of roughly 1000 in this example. The fluctuations are organized in thin, stretched out tubes which are aligned with the background magnetic field.

So how about the time domain? The frequencies of the fluctuations tend to span a fairly wide range around an average value which correlates with the characteristic frequency v_{ti}/R . For a device like ASDEX Upgrade, typical frequencies are of the order of a few 100 kHz. Moreover, time traces of fluctuation measurements do not exhibit any particular regularity (like periodicity). This kind of behavior suggests that the system is in a turbulent state, exhibiting spatio-temporal chaos.

What causes these fluctuations?

A plasma confined in a toroidal magnetic field is subject to a large number of waves and instabilities. The latter are often driven by the unavoidable density and temperature variations, and they are categorized in terms of macroinstabilities and microinstabilities, depending on their perpendicular scale lengths. Macroinstabilities exhibit variations on the largest scales of the system both parallel and perpendicular to the background magnetic field. They are typically described in the context of magnetohydrodynamic theory, and further details are provided elsewhere in this Encyclopedia. Microinstabilities, on the other hand, have spatio-temporal scales which align with those of the experimentally observed fluctuations.

Typical examples include ion temperature gradient modes and trapped electron modes, both of which are covered in a number of existing textbooks like [Weiland \(1999\)](#) and [Horton \(2017\)](#). Any accurate description of these microinstabilities is to be based on a (gyro-)kinetic treatment, as will be discussed in more detail below. They have been suggested as possible sources of the observed fluctuations for many years, and more recently, theory and simulation has advanced to a point where quantitative predictions can be made and then compared to experimental measurements. This has been successful in numerous cases, establishing the notion that turbulent transport driven by microinstabilities is a key factor in setting the energy confinement time of a fusion device. A snapshot from a numerical simulation with the gyrokinetic turbulence code GENE, described in [Jenko et al. \(2000\)](#) and [Görler et al. \(2011\)](#), is shown in [Fig. 1](#).

Turbulent transport: Bohm vs. gyro-Bohm

As in others physical systems like fluids or gasses, turbulence in plasmas is an excellent agent for transporting particles, momentum, and energy from one spatial domain to another. It is one of the key challenges for fusion research to understand, predict, and control turbulent transport.

A first question that arises in this context is: How is it possible that small-amplitude fluctuations (of the order of a percent or less) can have such a dramatic effect? A simple estimate of the turbulent ion heat diffusivity χ_i arising from the microinstabilities mentioned above can be obtained via the analogy to a random walk. Taking the size of a step Δx and the time elapsed between successive steps Δt to be given, respectively, by the perpendicular correlation length of the turbulence of several ion gyroradii and the inverse characteristic frequency of R/v_{ti} , the resulting turbulent heat diffusivity, $(\Delta x)^2/\Delta t$, can be estimated as

Fig. 1 Snapshot from a numerical simulation of microturbulence in the ASDEX Upgrade tokamak with the gyrokinetic code GENE. As described in the main text, the fluctuations of plasma density and temperature form thin, stretched out structures which are aligned with the background magnetic field. In the core plasma, the fluctuation amplitude is on the order of a percent.

$$\chi_i \sim \chi_g \equiv \rho_i^2 v_{ti} / R$$

Using the numbers quoted above for ASDEX Upgrade, this corresponds to a turbulent diffusivity of a few m^2/s , in line with what can be inferred from experimental measurements.

A second fundamental question is: How does this turbulent transport scale with system size? In other words, should we expect larger fusion devices (say, future power plants) to behave better or worse than present-day experiments in this regard? Well, for a given particle species, we obtain the scaling $\chi_i \propto T_i^{3/2} R^{-1} B^{-2}$. Given that all of three of these parameters will increase in ITER w.r.t. ASDEX Upgrade only by a moderate factor (of about 2–3.5), χ_i will roughly remain the same, namely in the range of a few m^2/s , provided that the employed scaling formula is correct. It is based on the assumption that the perpendicular correlation lengths of the turbulent fluctuations are related to ρ_i and do not increase with the system size. This idea has been questioned from time to time, however, and it was suggested instead that the perpendicular correlation lengths may in fact scale as $(\rho_i R)^{1/2}$, implying that radial variations of the density and temperature profiles (related to R) are a key ingredient in determining this quantity. This would lead to

$$\chi_i \sim \chi_B \equiv \rho_i v_{ti}$$

which is significantly larger than the estimate provided above. Given that χ_b is equivalent to the diffusion coefficient conjectured by David Bohm back in 1949 (up to a constant prefactor), it is called “Bohm diffusion.” And since χ_g involves an extra factor of ρ_i/R (which can be as small as $\sim 10^{-3}$ in ITER), it is termed “gyro-Bohm diffusion.” Obviously, if the Bohm scenario applied, this would be bad news for fusion research. Numerical simulations and experimental investigations suggest, however, that the majority of experimental situations is well described by the gyro-Bohm formula, in particular in larger devices.

On the nature of plasma turbulence

The most widely known example of a turbulent system is turbulence in a conventional fluid, as described by the well known Navier-Stokes equations. Plasma turbulence, on the other hand, deviates substantially from this scenario. In the following, we will first briefly describe the nature of turbulence in fluids and then highlight similarities and differences observed in plasma turbulence.

Turbulence in fluids

In conventional fluids, turbulent flows consist of eddies (or vortices) of a wide range of sizes which interact with each other non-linearly. Large eddies, typically driven by an external force, decay into somewhat smaller ones, which in turn decay into somewhat smaller ones etc. until viscous forces come into play and dissipate the fluctuations at small scales. This means that energy enters the system at the large drive scales and leaves at the small viscous scales. The scale range in between, characterized by the conservative transfer of energy in the absence of drive or dissipation, is called inertial range. In certain laboratory and natural systems, this inertial range can span many orders of magnitude. An excellent introduction to fluid turbulence can be found in [Davidson \(2015\)](#).

As it turns out, turbulence represents an interesting example of the coexistence of chaos and order. While the detailed dynamics in space and time depends very sensitively on all kinds of factors like the initial and boundary conditions or tiny perturbations of the system, the *averaged* properties of the turbulent flows in a saturated, quasi-steady state exhibit the existence of strongly reduced sensitivity and robust order in a *statistical* sense. It is considered a key challenge of turbulence research to predict these properties directly

from the Navier-Stokes equations. While a lot of progress has been made along these lines since the pioneering work of Kolmogoroff, Heisenberg, and others in the 1940s, a comprehensive theory of fluid turbulence remains elusive at this point.

Turbulence in astrophysical plasmas

Astrophysical systems are usually hot and/or dilute. This implies they are in a plasma state. Moreover, their dynamics tend to be strongly driven, inducing turbulence. The physics of turbulent plasmas is therefore a key aspect of many branches of astrophysical research. However, the basic nature of turbulence in astrophysical plasmas deviates from that in Navier-Stokes systems in fundamental ways. At the heart of this difference lies the fact that these plasmas—in contrast to conventional fluids—are characterized by the existence of waves. Therefore, turbulence has to be understood in terms of a large sets of waves (not eddies) interacting with each other.

Given the competition of linear and nonlinear dynamics in plasma turbulence, the question arises to which degree the properties of waves are retained or destroyed in a turbulent environment. If the influence of the nonlinear dynamics would be small, a system could be thought of as a collection of weakly interacting linear waves in the context of (the well-established) *wave turbulence theory*. If, on the other hand, the nonlinear dynamics would be dominant, the linear wave properties would become more or less irrelevant, and the system would resemble a turbulent fluid. As was first pointed out in Goldreich and Sridhar (1995), astrophysical plasmas tend to live exactly in the middle between these two extremes. The linear wave properties are perturbed substantially, but not wiped out completely. This feature is generally referred to as *critical balance*. In the turbulence state, many amplitude and phase relations between pairs of fluctuating quantities as prescribed by the linear dynamics are retained to some degree in fully developed turbulence. Meanwhile, conventional wave turbulence theory is not directly applicable. Instead, a new theory of strong wave turbulence needs to be developed.

Microturbulence in fusion plasmas

Interestingly, many other physical systems—from rotating fluids to Bose-Einstein condensates—share many of these features, as is discussed, e.g., in Nazarenko (2011). This actually includes microturbulence in fusion plasmas. A turbulent fusion plasma consists of a large collection of microinstabilities which interact with each other through nonlinear processes. This happens in a way that allows various linear wave properties to survive in the turbulent environment. The microinstabilities, of which there exist a number of different types, grow exponentially in time until their amplitudes reach a level at which linear and nonlinear terms in the underlying equations are in rough balance. At this point, nonlinear saturation takes place, and the system enters a quasi-steady state whose statistical properties, like turbulent transport coefficients, are of primary interest.

An example for this kind of dynamics is shown in Fig. 2. Here, the frequencies ω of the relevant microinstabilities (in this case, trapped electron modes and electron temperature gradient modes, both moving in the electron diamagnetic drift direction as indicated by the negative sign) are shown as a function of the perpendicular wavenumber k_y , with the data taken from a GENE simulation. For normalization, the quantities c_s and ρ_s are introduced; these correspond to v_{ti} and ρ_i but are evaluated using the electron temperature instead of the ion temperature. For linear modes, there exists a unique $\omega(k_y)$ relationship which is shown in red. In a nonlinear simulation, analyzing time traces of turbulent fluctuations associated with a particular value of k_y , one obtains a frequency distribution function whose center $\bar{\omega}$ and width $\Delta\omega$ are indicated in blue. It is important to note that $\Delta\omega \ll \bar{\omega}$ and $\bar{\omega} \sim \omega$. This finding is highly non-trivial and suggests that the linear modes interact nonlinearly in a significant way, while retaining their basic nature.

Fig. 2 Linear and nonlinear frequencies ω of the relevant microinstabilities as a function of the perpendicular wavenumber k_y , with the data taken from a GENE simulation; see Görler and Jenko (2008). These results suggest that the linear modes interact nonlinearly in a significant way, while retaining their basic nature, providing the basis for the development of reduced models of turbulent transport. Further details are provided in the main text.

The same conclusions can be drawn from inspection of other linear mode properties, like cross phases or amplitude ratios between pairs of fluctuating quantities, as is demonstrated, e.g., in [Dannert and Jenko \(2005\)](#). This provides the basis for the development of reduced models of turbulent transport which exploit these “quasilinear” properties and are very popular for providing (initial) interpretations of experimental results. In this context, it is assumed that the quasi-stationary turbulent state can be described by a superposition of linear waves, whose amplitudes are given by suitable simplified models that attempt to capture the essence of various nonlinear saturation mechanisms. Further details are provided, e.g., in [Horton \(2017\)](#).

Theoretical description of turbulent transport in fusion plasmas

A quantitative description of microturbulence in fusion plasmas needs to take into account a range of kinetic effects (like Landau damping and Finite Larmor Radius effects) which are beyond the scope of (standard) fluid theory or magnetohydrodynamics. In principle, one could solve the Vlasov equation (i.e., the collisionless Boltzmann equation) for the distribution function in six-dimensional position-velocity space for each particle species, calculating the self-consistent electric and magnetic fields with the help of Maxwell’s equations. Such a brute-force approach would imply that one needs to resolve many phenomena at extremely small spatio-temporal scales (like so-called Langmuir waves) which are irrelevant to the problem at hand. Fortunately, it was realized in the fusion theory community around the 1980s that a much more suitable plasma description exists, namely gyrokinetic theory.

Gyrokinetic theory of strongly magnetized plasmas

In fusion plasmas, the electrically charged electrons and ions move on helical trajectories along magnetic field lines. The characteristic frequencies of this gyromotion exceed the typical frequencies of the turbulent fluctuations by a substantial amount. Given this time scale separation, it is therefore natural to try to remove the fast dynamics of gyration from the equations analytically, considering the centers of charged rings instead of the particles themselves. Exploiting, in addition, various experimentally observed characteristics of the turbulent fluctuations (small amplitude, spatial anisotropy etc.), one can reduce the fully kinetic model to a gyrokinetic one, with Maxwell’s equations being replaced by a gyrokinetic version thereof.

A visual representation of this procedure is provided in [Fig. 3](#). A charged particle embedded in a strong magnetic field exhibits a helical trajectory, and the particle position $\mathbf{x}$ (open circle) can be expressed in terms of the guiding center position $\mathbf{X}$ (filled circle) according to

$$\mathbf{x} = \mathbf{X} + \mathbf{r}$$

Fig. 3 Visual representation of the basic idea behind gyrokinetics. A charged particle embedded in a strong magnetic field exhibits a helical trajectory about the time-varying guiding center position. The motion of the particle is replaced by the motion of the guiding center, with the forces acting on the particle being averaged along respective rings. Further details can be found in the main text. Taken from Howes GG, Cowley SC, Dorland W, Hammett GW, Quataert E, and Schekochihin AA (2006) Astrophysical gyrokinetics: Basic equations and linear theory. *The Astrophysical Journal* 651: 590.

with

$$\mathbf{r} \equiv \frac{\mathbf{b} \times \mathbf{v}}{\Omega}$$

where $\mathbf{b}$ is the unit vector along the magnetic field, $\mathbf{v}$ is the particle's velocity, and $\Omega = (qB)/(mc)$ is the particle's gyrofrequency, all evaluated at the current particle position. The guiding center position tends to follow the unperturbed magnetic field B_0 (long-dashed line), but deviates from it due to perpendicular drifts (the sum of the curvature, ∇B , and $E \times B$ drifts) and magnetic field perturbations B (solid line). Given that the gyromotion is very fast in comparison with all other time scales of interest, it is averaged out. In this context, the motion of the particle is replaced by the motion of the guiding center, and the forces acting on it are averaged along respective rings. Here, the characteristic perpendicular and parallel length scales of the plasma fluctuations are denoted by $l_{\parallel}$ and $l_{\perp}$, respectively. As discussed before, $l_{\parallel} \gg l_{\perp}$.

Derivation of the gyrokinetic equations

While it may be natural to think that gyrokinetic theory is best derived from kinetic theory on the level of equations of motion, it turns out that there is a much better approach. In the context of classical mechanics, it is shown that a system's dynamics can be described with the help of a so-called Lagrangian. This mathematical object allows you to readily derive the equations of motion by evaluating the Euler-Lagrange equations. More information is provided in textbooks on Classical Mechanics like [Goldstein \(2013\)](#). So the challenge becomes how to derive a gyrokinetic Lagrangian from the kinetic one. The description of all explicit steps that are required to achieve this task is clearly beyond the scope of this text. The interested reader may want to consider exploring the overview paper by [Brizard and Hahm \(2007\)](#) and some of the literature cited therein. In the following, we will simply write down the Lagrangian of a kinetic system, its gyrokinetic counterpart, and the resulting gyrokinetic equations of motion.

At this point, one should recall that the equations of motion for a charged particle in prescribed electric and magnetic fields,

$$\dot{\mathbf{x}} = \mathbf{v}, \quad \dot{\mathbf{v}} = \frac{q}{m} \left(\mathbf{E} + \frac{\mathbf{v}}{c} \times \mathbf{B} \right)$$

can be derived from the Lagrangian

$$\mathcal{L} = \left(\frac{q}{c} \mathbf{A} + m\mathbf{v} \right) \cdot \dot{\mathbf{x}} - \left(\frac{m}{2} v^2 + q\phi \right)$$

via the Euler-Lagrange equations,

$$\frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \dot{q}_i} - \frac{\partial \mathcal{L}}{\partial q_i} = 0$$

with $\mathbf{q} = (\mathbf{x}, \mathbf{v})$ as a six-component vector. Here, the vector and scalar potentials, $\mathbf{A}$ and ϕ , as well as the electric and magnetic fields,

$$\mathbf{E} = -\nabla\phi - \partial_t \mathbf{A}/c, \quad \mathbf{B} = \nabla \times \mathbf{A}$$

are generally dependent on $\mathbf{x}$ and t .

Neglecting—for the moment—fluctuations and transitioning from particle coordinates $(\mathbf{x}, \mathbf{v})$ to guiding center coordinates $(\mathbf{X}, v_{\parallel}, \mu, \varphi)$, where $\mathbf{X}$ is the guiding center position, $v_{\parallel}$ is the component of $\mathbf{v}$ parallel to the local magnetic field, $\mu \equiv (mv_{\perp}^2)/(2B)$ is the magnetic moment, and φ is the gyrophase, one obtains a new Lagrangian, formulated now with respect to the guiding center coordinates,

$$\mathcal{L} = \left(\frac{q}{c} \mathbf{A} + mv_{\parallel} \mathbf{b} \right) \cdot \dot{\mathbf{X}} + \frac{\mu B}{\Omega} \dot{\varphi} - \left(\frac{m}{2} v_{\parallel}^2 + \mu B + q\phi \right)$$

where $\mathbf{A}$ and ϕ (as well as B and Ω) depend on the guiding center position $\mathbf{X}$, not on the particle position $\mathbf{x}$. The resulting Euler-Lagrange equations read

$$\dot{\mathbf{X}} = v_{\parallel} \mathbf{b} + (B/B^*) (\mathbf{v}_E + \mathbf{v}_{\nabla B} + \mathbf{v}_c)$$

$$\dot{v}_{\parallel} = (q\mathbf{E} - \mu \nabla B) \cdot \dot{\mathbf{X}} / (mv_{\parallel}), \quad \dot{\mu} = 0, \quad \dot{\varphi} = \Omega$$

where

$$\mathbf{v}_E \equiv \frac{c}{B^2} \mathbf{E} \times \mathbf{B}, \quad \mathbf{v}_{\nabla B} \equiv \frac{\mu}{m\Omega} \mathbf{b} \times \nabla B, \quad \mathbf{v}_c \equiv \frac{v_{\parallel}^2}{\Omega} \mathbf{b} \times (\mathbf{b} \cdot \nabla) \mathbf{b}$$

are, respectively, the $E \times B$ drift, ∇B drift, and curvature drift, and

$$B^*/B = \mathbf{b} + (v_{\parallel}/\Omega) \nabla \times \mathbf{b}, \quad B^* = \mathbf{b} \cdot \mathbf{B}^*$$

In the next step, small fluctuations are taken into account, assuming that they satisfy the experimentally observed characteristics of $\omega \ll \Omega$ and $k_{\parallel} \ll k_{\perp}$. This leads to additional terms in the Lagrangian,

$$\mathcal{L}_1 = \left(\frac{q}{c} \bar{\mathbf{A}}_{\parallel 1} \mathbf{b}_0 \right) \cdot \dot{\mathbf{X}} - \left(\mu \bar{B}_{\parallel 1} + q \bar{\phi}_1 \right)$$

and associated terms in the equations of motion. In particular, three new drifts are introduced,

$$\mathbf{v}_{m1} \equiv v_{\parallel} \left(\bar{\mathbf{B}}_{\perp 1} / B_0 \right), \quad \mathbf{v}_{E1} = \frac{c}{B^2} \bar{\mathbf{E}}_1 \times \mathbf{B}, \quad \mathbf{v}_{B1} = \frac{\mu}{m\Omega} \mathbf{b} \times \nabla \bar{B}_{\parallel 1}$$

with $\bar{\mathbf{E}}_1 = -\nabla \bar{\phi}_1 - \mathbf{b} \partial_t \bar{A}_{\parallel 1} / c$ and $\bar{\mathbf{B}}_{\perp 1} = \nabla \times \left(\bar{A}_{\parallel 1} \mathbf{b} \right)$. Here, $\mathbf{v}_{m1}$ describes the motion perpendicular to the background magnetic field due to particles following fluctuating field lines, while $\mathbf{v}_{E1}$ and $\mathbf{v}_{B1}$ describe, respectively, contributions to the $E \times B$ drift and ∇B drift due to fluctuations in the electrostatic potential and parallel magnetic field. The overbar designates fluctuating quantities which are gyroaveraged appropriately.

The corresponding gyrokinetic Vlasov equation describing the time evolution of the distribution function F in five-dimensional gyrocenter space $\mathbf{Z} = (\mathbf{X}, v_{\parallel}, \mu)$, with the gyrophase dependence removed, can be written in advection form as

$$\left(\frac{\partial}{\partial t} + \dot{\mathbf{Z}} \cdot \frac{\partial}{\partial \mathbf{Z}} \right) F(\mathbf{Z}, t) = 0$$

It is the first cornerstone of gyrokinetics. The second one is the gyrokinetic version of Maxwell's equations, which is needed to calculate the self-consistent fluctuating electromagnetic fields. For further details on this topic and on gyrokinetic theory in general, the interested reader is referred to [Brizard and Hahm \(2007\)](#). The goal of the present introduction was merely to provide a flavor of the kind of physics and mathematics underlying state-of-the-art computations of turbulent transport in fusion devices.

Computational gyrokinetics

The complete system of gyrokinetic equations, including a modified version of Maxwell's equations, constitutes a set of nonlinear partial differential equations for a distribution function that depends on the three spatial coordinates, two velocity space coordinates, and time. As can be expected, it is impossible to provide exact analytic solutions to these equations for realistic cases. Instead, one has to resort to numerical solutions. Several gyrokinetic simulation codes have been developed over the years, and most of them fall into one of the following two categories.

- Particle-in-cell (PIC) codes adopt a Lagrangian view of the phase space dynamics, exploiting the fact that the value of the distribution function of a given particle species does not change along phase space trajectories. This can be expressed mathematically in terms of $df/dt = 0$, i.e., the total time derivative of the distribution function vanishes. One thus distributes a very large number of so-called marker particles across phase space and numerically computes their trajectories. To obtain the self-consistent electric and magnetic fields at each time step, the resulting charge and current densities are calculated on a fixed spatial grid, and the field equations are solved on that grid. This unique combination of numerical techniques is what gives this approach its name. The greatest advantage of the PIC approach may be that it is intuitively accessible, while its most significant drawback is the existence of numerical noise due to the use of a Monte-Carlo-type sampling approach. The accuracy of a given simulation increases only as $N^{-1/2}$ where N is the number of particles used in the simulation.
- Continuum codes, on the other hand, are based on a Eulerian view of the phase space dynamics, often adopting numerical methods originally developed in the context of Computational Fluid Dynamics (CFD). Here, the basic idea is to define small volumes in phase space and monitor how many particles enter and leave each of these volumes per time unit. In practice, combinations of finite difference, finite volume, and spectral methods often tend to be employed. In terms of time stepping, explicit methods tends to dominate, but the use of combinations of explicit and implicit methods has also been explored. Continuum codes are less straightforward to develop, often requiring highly original combinations of numerical methods, but they can readily be adapted and optimized for a large range of situations and do not suffer from numerical noise. In most cases, higher order methods are employed, ensuring fast convergence with increasing resolution.

Both types of codes have been used successfully to study fundamental aspects of turbulence in fusion plasmas and to interpret specific experimental results, and an overview of key activities in this area up to a certain point is provided in [Garbet et al. \(2010\)](#). Due to their complementary strengths, they are sometimes used in tandem to explore certain physics questions. Running realistic cases with high numerical resolution requires significant computer resources. For many years, gyrokinetic simulation has therefore been at the forefront of High Performance Computing (HPC). A lot of effort is put into the parallelization and optimization of gyrokinetic codes on the world's largest and most powerful supercomputers. This is the prerequisite for exploring a number of key physics issues in magnetic confinement fusion research.

Towards validated and predictive gyrokinetic simulations

Over the past two decades or so, gyrokinetic simulations have become increasingly comprehensive and realistic, allowing for direct comparisons between simulation results and experimental observations. In a large number of dedicated validation studies, the ability of these tools to provide a quantitative description of plasma microturbulence has been tested successfully. Both the

transport levels and various detailed properties of turbulence fluctuations in experiments have been recovered in gyrokinetic simulations. While, up to this point, the goal of such investigations has been to help interpret existing experiments, in particular with respect to the observed turbulent transport levels in the core region of fusion plasmas, it is becoming increasingly clear that we are about to enter a new phase in this kind of endeavor.

Emerging new focus areas include the interaction of plasma turbulence with other physical processes like MHD instabilities or energetic particles, a quantitative description of turbulence in the core of stellarators, and the treatment of the boundary region of fusion devices. Moreover, there is a growing expectation within the scientific community for these kinds of simulations to become truly predictive. This will be needed, in particular, to optimize the design and operation of future fusion experiments and power plants. The guidance provided by gyrokinetic simulations will be invaluable in this context, allowing for significant savings of development time and financial resources on the experimental side, thus accelerating fusion research. Obviously, such an ambitious research program calls for the inclusion of state-of-the-art techniques from applied mathematics and computer science. The main goal is to quantify the physics processes driving turbulence and to control the turbulent transport in various ways, to maximize the energy confinement time for any given device, avoid impurity accumulation, and help provide solutions to the problem of heat and particle exhaust.

Controlling turbulent transport

Turbulent fluctuations and the associated transport across flux surfaces have been observed in every fusion experiment that has been built and operated in the last few decades. While collisional (“neoclassical”) transport is known to also be significant under certain circumstances, including the core regions of almost all stellarators, it is *turbulent* transport that usually sets the energy confinement time of a given device, and thus a key performance indicator. Interestingly, several kinds of improved confinement regimes have been identified experimentally. And gyrokinetic simulations are being applied to gain a deeper understanding of the underlying physical processes. In the following, we will provide an overview of some recent and ongoing activities along these lines.

Improved confinement regimes: The L-H transition

As is explained elsewhere in this Encyclopedia, there exist several improved confinement regimes—with respect to the so-called low confinement mode or L-mode, which provides a baseline level of confinement in most magnetic confinement devices—that have been discovered experimentally. The most prominent example is the so-called high confinement mode or H-mode. The phenomenon of the L-H transition was first observed in the early 1980s in the ASDEX tokamak at Garching, Germany, see [Wagner \(1984\)](#), and it has been confirmed in countless other devices since then. The H-mode is the default scenario for high-performance operation in virtually all existing and planned tokamaks, including ITER. Therefore, the development of a detailed understanding of the L-H transition is of crucial importance to the fusion community, and reviews are provided in [Connor and Wilson \(2000\)](#), [Wagner \(2018\)](#), and [Bourdelle \(2020\)](#).

From the experimental side, one observes that the plasma exhibits a sudden transition to a new state which is characterized by a transport barrier—i.e., a narrow radial region of only several cm with strongly reduced turbulent heat and particle transport, leading to steep temperature and density profiles—near the plasma boundary, just inside the last closed flux surface. An example

Fig. 4 L-H transition dynamics as observed in the ASDEX tokamak: (A) development of the edge density profile during the transition; (B) radial variation of edge density fluctuations for the same five time points. Taken from Wagner F, et al. (1991) *Plasma Physics and Controlled Nuclear Fusion Research*, vol. 1, p. 277. Vienna: IAEA.

from the ASDEX tokamak is shown in Fig. 4. Moreover, one finds that the transition occurs once the heating power exceeds a certain threshold. The latter can be described by an empirical formula reported in Martin (2008),

$$P_{th} = 0.049 \bar{n}_e^{0.72} B_t^{0.80} S^{0.94}$$

where P_{th} is the power threshold in MW, $\bar{n}_e$ is the line-averaged density in 10^{20} m^{-3} , B_t is the toroidal magnetic field in T, and S is the plasma surface area in m^2 . For ITER, with $B_t = 5.3 \text{ T}$ and $S = 678 \text{ m}^2$, one obtains $P_{th} = 52 \text{ MW}$ if one assumes $\bar{n}_e = 0.5 \cdot 10^{20} \text{ m}^{-3}$, with the 95% confidence interval extending all the way from 28 to 96 MW. For smaller or larger values of $\bar{n}_e$, all of these numbers have to be rescaled by a factor of $(\bar{n}_e/0.5)^{0.72}$, of course. Given that, at the beginning of its operation, ITER will have 73 MW of

Fig. 5 Edge radial electric fields E_r —along with the resulting $E \times B$ shearing rates $\omega_{E \times B}$ and ion pressure gradients ∇p_i —measured in different confinement regimes of the ASDEX Upgrade tokamak, as a function of the radial coordinate ρ_{pol} . In L-mode, the shearing rates are roughly comparable to the typical frequencies of the turbulent fluctuations, while in H-mode, they exceed them by about an order of magnitude, suggesting the existence of a pronounced suppression effect. (I-mode is another improved confinement regime which is not discussed here.) Taken from Viezzer E., et al. (2013) High-accuracy characterization of the edge radial electric field at ASDEX Upgrade. *Nuclear Fusion* 53: 053005.

additional heating power, H-mode access at higher density might become marginal. This highlights the necessity for the development of a predictive computational capability for the L-H transition.

One of the key findings in the context of L-H transition studies is the fact that a large radial electric field is created near the transition from open to closed magnetic field lines at the separatrix, as shown in Fig. 5, which is taken from Viezzer et al. (2013). Such an electric field leads to $E \times B$ flows within flux surfaces which vary rapidly as a function of the flux surface label, resulting in strong shear flows which can be characterized by the so-called $E \times B$ shearing rate $\omega_{E \times B}$, i.e., the radial derivative of the $E \times B$ drift velocity associated with a given radial electric field. As it turns out, these sheared flows can be driven either by the turbulence itself or by a number of other mechanisms (like collision-induced effects in the presence of steep plasma profiles or highly energetic ions in the near-edge region which leave the plasma). They distort and destroy the turbulent structures associated with the underlying driving microinstabilities, thus suppressing the turbulence. As a consequence, the temperature and density profiles increase rapidly in this radial region, forming a pedestal-type structure.

The turbulence suppression mechanism is illustrated in Fig. 6, taken from Itoh et al. (1999), using a simplified geometry. Here, the magnetic field points in the z direction, while x and y represent, respectively, the radial and poloidal directions. Assuming that the poloidal component of the $E \times B$ velocity can be described as $V_y = S_v x$, we consider the time evolution of a turbulent structure which is circular at $t = 0$. At a later point in time, the circle of radius L will get distorted into an ellipse, with its top being displaced w.r.t. its bottom by $LS_v t$. Given that the area of the structure is preserved, one can easily calculate that $L_\perp = L(1 + S_v^2 t^2)^{-1/2}$. This means that for $t \gg S_v^{-1}$, the perpendicular wavenumber increases linearly with time, triggering linear and nonlinear damping mechanisms which reduce the turbulence level. The temperature and density profiles steepen accordingly, similar to what happens when one puts an extended insulating layer around an object (like a building or a container).

Given that one finds experimentally that the ratio of the core and pedestal temperatures tends to be roughly constant in many relevant regimes, the core profiles will adapt to these changes in the boundary conditions. This can be explained theoretically by the fact that one of the most important microinstabilities driving the turbulence, the ion temperature gradient mode, is only destabilized once a threshold in $\nabla T_i/T_i$ is exceeded. (Similar consideration also apply to other types of microinstabilities, like trapped electron modes.) The pressure in the plasma center can thus be increased substantially, providing better conditions for a fusion plasma to satisfy the Lawson criterion for a burning plasma.

While individual aspects of the formation of transport barriers have been identified and studied theoretically and computationally in isolation, a comprehensive and self-consistent description of an L-H transition remains elusive. Apparently, the type of gyrokinetic models being applied to this problem as of today are not yet sufficiently comprehensive. There is a general consensus in the community that beyond the well-established capabilities of core codes—which include collisions, magnetic field fluctuations, and cross-scale coupling effects—the following issues have to be addressed in any case:

- A simulation domain covering the entire plasma boundary, involving both the outer core region and the scrape-off layer (SOL), dealing with the complexities introduced by the existence of a magnetic separatrix (last closed flux surface) and open magnetic

Fig. 6 Effect of sheared $E \times B$ flows—resulting from a radially dependent radial electric field—on turbulent structures, using a simplified geometry. Here, the magnetic field points in the z direction, while x and y represent, respectively, the radial and poloidal directions. Further details are provided in the main text. Taken from Itoh K, Itoh SI and Fukuyama A (1999) *Transport and Structural Formation in Plasmas*. Institute of Physics Publishing.

field lines. This implies that the standard methods for adapting the coordinate system to the background magnetic field as used in the core are not applicable here.

- A self-consistent treatment of the plasma background and fluctuations, based on the fact that fluctuation levels in the SOL can be as large as several 10%. This implies that codes optimized for the core region cannot be applied, and that new codes have to be developed, based on adequate numerical schemes.
- The inclusion of additional particle species, some of which are not ionized at all or only partially ionized. This is due to the fact that the plasma in the boundary region is relatively cold and close to the wall, which can act as a source of particles. This also implies that one needs to deal with the serious computational challenges associated with the treatment of plasma-wall interaction effects.

Such tools are currently under development, raising the expectation that a self-consistent description of the L-H transition may gradually come within reach. Various synergies with existing fluid boundary codes can be exploited in this context.

Meanwhile, existing gyrokinetic codes are being used to investigate specific aspects of the L-H transition. This includes, in particular, the nature of the turbulent transport in the edge of an established L-mode and H-mode discharge, various mechanisms to create shear flows in the plasma boundary, and effects of neutrals and impurities on the edge turbulence. Based on these building blocks, it is planned to gradually develop a comprehensive picture of the physics of this intriguing phenomenon. Once validated against existing experiments, the goal would be to apply such simulation capabilities to predict the performance of ITER and DEMO.

We note in passing that there also exists a range of other improved confinement regimes which is being studied. Moreover, transport barriers also occur in the core region, where they are called internal transport barriers (as opposed to the edge transport barriers discussed above). Empirically, their formation also depends on the occurrence of favorable local plasma conditions, e.g., in terms of magnetic shear or flow shear.

Transport-by-design in stellarators

A fascinating new research opportunity in the context of turbulent transport optimization is provided by the advent of optimized stellarators. Whereas the cross-field transport of particles and heat in the core region (but not the edge region) of conventional stellarators tends to be dominated by collisional (i.e., neoclassical) processes, a new situation presents itself to the fusion community in the case of optimized stellarators like Wendelstein 7-X (W7-X). Here, the magnetic geometry has been optimized in a way so that collisional transport processes are minimized. As recent experimental transport studies in W7-X have revealed, turbulence becomes the dominant transport mechanism under these circumstances even in the core region. Given that the magnetic field structure is much more complex than that in tokamaks, the question arises if this feature can be exploited to control the turbulence. First theoretical and computational studies have confirmed the suspicion, paving the way towards a realization of the notion of transport-by-design in stellarators.

As has been discussed above, turbulence in fusion plasmas is driven by various kinds of microinstabilities whose properties are determined by the structure of the background magnetic field and the density and temperature profiles of the plasma, and which tend to persist to some degree in the saturated quasi-steady state, as discussed above. Given that the magnetic field of a non-axisymmetric stellarator has many more degrees of freedom than an axisymmetric tokamak, this feature can be exploited to influence the properties of turbulent transport in significant ways, as has been shown in gyrokinetic simulations (see Fig. 7).

Since any kind of optimization calls for a very large number of model evaluations, an approach involving high-resolution gyrokinetic simulations directly is not viable, given that each single simulation typically requires significant resources on large-scale supercomputers. A more realistic approach is to develop an approximate theoretical framework which allows to identify

Fig. 7 Snapshot from a numerical simulation of microturbulence in the Wendelstein 7-X stellarator with the gyrokinetic code GENE-3D; see [Maurer et al. \(2020\)](#). Such simulations can be used to systematically investigate the effects of various aspects of the magnetic geometry on the turbulent transport, supporting the notion of transport-by-design.

important parameter dependencies, carry out a limited number of gyrokinetic simulations, and evaluate them carefully in the context of this framework. On this basis, reduced transport models can be constructed and then applied within suitable optimization procedures. Such approaches are currently being developed and will be used to aid the design of future stellarator devices.

Conclusions and outlook

Given the high temperatures and low densities of magnetically confined fusion plasmas, the collision frequencies in these systems tend to be extremely low, calling for a kinetic approach instead of a fluid one. Fortunately, many small spatio-temporal scales which are irrelevant to the problem at hand can be eliminated analytically from the fundamental equations. The resulting model is called gyrokinetics, based on the idea of averaging out the fast gyromotion of the charged particles, thus reducing the number of phase space dimensions from six to five by removing the gyrophase dependence. The resulting set of nonlinear partial differential equations requires a numerical treatment, and two main types of codes have been developed, PIC codes and continuum codes, which are used in a complementary fashion.

Gyrokinetic simulation has come a long way since its inception in the 1980s. Following a phase of pioneering studies using very simplified physical settings, there was a significant increase regarding the level of realism since about the year 2000. Over the last decade or so, a series of careful validation studies has been carried out successfully, demonstrating the validity and power of gyrokinetic simulation. The logical next step is to gradually transition from interpretive to predictive studies, providing guidance for the design of next-generation fusion experiments and first power plants. This ambitious plan will be aided by the emergence of exascale supercomputers in the early 2020s, allowing scientists to carry out computations involving more than 10^{18} floating point operations per second.

Introduction

In magnetic-fusion confinement devices such as tokamaks, to remain confined and produce fusion power, the plasma must be maintained in a force-balance equilibrium state and stable to perturbations around this state. To keep the plasma away from the surrounding vacuum vessel, the expanding hot-plasma pressure force, and the centrifugal force if the plasma is rotating, must be balanced by a counter magnetic force driven by electrical currents flowing in the external coils. As schematically illustrated in Fig. 1A and B, a stationary ball sitting in the bottom of a valley represents a stable equilibrium state, whereas the one sitting on the top of a hill represents an unstable equilibrium state.

Magnetohydrodynamics (MHD) (Bateman, 1978; Freidberg, 1982) provides a useful model to describe and evaluate this macroscopic plasma equilibrium and stability state by considering the plasma as a conducting fluid confined in a restricted region of space by the electromagnetic force from an externally imposed magnetic field. The magnetic field can be conveniently visualized and represented using magnetic field lines (Boozer, 2005). In an axisymmetric toroidal tokamak device, the magnetic field lines form a set of nested magnetic surfaces in a donut shape. The geometric and topological properties of the magnetic surfaces such as the aspect ratio, elongation, triangularity and squareness play important roles in determining the stability and performance of tokamak plasmas, and can be controlled using a set of external poloidal-field coils.

An important MHD application is to design an optimal set of external poloidal magnetic-field coils to produce a target plasma equilibrium shape that is stable to instabilities. An essential magnetic-fusion research element is to develop the physics basis to support such activities. This requires design and performance of experiments to test the equilibrium and stability properties of the plasma, development and validation of MHD equilibrium and stability physics models to explain the experimental observations, and development of diagnostics and computational tools to accurately measure and efficiently reconstruct the plasma state to interpret the measurements and facilitate the validation.

In an ideal perfectly conducting plasma, the plasma is tied to the magnetic surfaces. In the absence of collisions among ions and electrons and without large drift motions due to magnetic-field gradient and curvature in the magnetic-field lines, the magnetic surfaces act as a container to keep the plasma away from the surrounding vacuum-vessel wall and plasma facing components (PFCs). The hot plasma pressure and current flowing along the magnetic field lines can act as free-energy sources to drive the plasma away from the desired equilibrium and into various unstable states depending on the particular plasma operating configurations and conditions. The tension and shear in the magnetic-field lines can act as restoring forces to stabilize and keep the plasma in a stable equilibrium state. An excessive amount of plasma stored energy relative to the confining toroidal magnetic field energy

Fig. 1 (A) A stable equilibrium state, (B) an unstable equilibrium state.

or a large amount of flowing plasma current relative to the confining toroidal magnetic-field coil current can drive MHD instabilities that can potentially damage and shorten the lifetime of the confining device PFCs and in-vessel structures.

Two useful physics parameters to describe these important plasma stability properties are the safety factor q and the plasma toroidal beta β_T . For an axisymmetric toroidal device such as a tokamak, these are defined as

$$q(\psi) = \frac{F(\psi)}{2\pi} \oint_{\psi} \frac{dl_p}{B_p} \frac{1}{R^2} \quad (1)$$

$$\beta_T = \frac{\int_0^{\Omega_B} P d\Omega}{\Omega_B B_{T0}^2 / 2\mu_0} \quad (2)$$

Here, B_T and B_p are the toroidal and poloidal component of the magnetic field $\mathbb{B}$ from the electric currents flowing within the plasma plus those flowing in the external toroidal and poloidal magnetic-field coils. $F(\psi) = 2\pi R B_T / \mu_0$ is the poloidal current stream function, R is the plasma major radius, ψ is the poloidal flux per radian of the toroidal angle, and B_{T0} is the vacuum toroidal magnetic field at the geometric center of the plasma boundary surface. The line integration in Eq. (1) is along a poloidal cross section of a magnetic flux surface labeled by ψ , $\Omega(\psi)$ is the volume enclosed by the magnetic surface ψ , and Ω_B is the plasma volume. The safety factor q describes the average pitch of the magnetic field lines along a magnetic surface weighted by the geometric properties of the surface. q represents the number of turns a magnetic field line has to traverse toroidally before completing a poloidal turn.

Additionally, depending on the plasma transport conditions, strong pressure or current gradients can develop locally in a small region near a transport barrier that can act as free-energy source to drive the plasma into an unstable state (Lao, 2000). In the tokamak high confinement mode (H-mode) regime (Wagner, 2007; Burrell et al., 1987), a large edge pedestal pressure gradient can develop leading to edge localized modes (ELMs) (Leonard, 2014). Large ELMs can shorten the life time of the divertor wall.

MHD is also applied to develop robust techniques to mitigate and control MHD instabilities (Igochine, 2015). At high β_T or low q , a small perturbation can lead to unstable plasma motion that strongly distorts the magnetic surfaces allowing the plasma to quickly release its thermal and magnetic energy in a very short time scale, which can potentially damage the PFCs and in-vessel structures. Additionally, at rational q surfaces the magnetic field lines close on themselves rather than spanning the entire surface. A magnetic perturbation that has toroidal and poloidal mode numbers in sync with the pitch of the magnetic field lines can then interact resonantly with the magnetic field and strongly distort the magnetic surfaces, thus allowing the heat flux to quickly transport and escape to the surrounding vacuum-vessel wall. Additionally, together with the plasma resistivity and toroidal asymmetry, magnetic islands and stochastic regions can form around the rational q surfaces within the plasma that can tear open the magnetic surfaces and allow particle and heat flux to also redistribute and escape to the vessel wall. Impurities sputtered from the wall can then enter and accumulate in the plasma and can lead to a radiation induced thermal collapse and rapid decay of the plasma current. The shrinkage of the current channel in the plasma column can make it susceptible to vertical displacement events (VDEs) and then disruption, which can potentially damage the device PFCs and in-vessel structures due to the large attached halo current induced in the surrounding wall (Boozer, 2012; Lao and Jensen, 1991; Lehnen et al., 2015; Clauser et al., 2019).

In this article, the physics principles of toroidal tokamak equilibrium and stability are first discussed, including the derivation of the MHD equations from the Boltzmann kinetic equation. This is then followed by a section on toroidal equilibrium including a description of equilibrium reconstruction and the inverse representation. MHD stability including linear stability and the energy principle, the effects of plasma resistivity, energetic particles, and plasma toroidal flow is then discussed. A discussion of major MHD instabilities including axisymmetric modes, internal kinks (IKs), resistive-wall modes (RWMs), edge localized modes (ELMs), tearing modes (TMs), and toroidal Alfvén eigenmodes (TAEs) then follows. The plasma response to external 3D magnetic fields and numerical tools to compute MHD instabilities are also described. Lastly, a short discussion of methods and techniques to mitigate and control plasma instabilities including disruptions is given.

Physics principles of toroidal equilibrium and stability

MHD model and equations

MHD is the most basic plasma model, incorporating most large-scale phenomena, and including all major instabilities. The model is formally derived from the fundamental Bogoliubov–Born–Green–Kirkwood–Yvon (BBGKY) (Bogoliubov, 1946) equations describing an N -body system of N_s charged particles of various species in an electromagnetic field $\mathbb{E}$ and $\mathbb{B}$, coupled with Maxwell's equations for the fields. Each individual particle with (vector) position $\mathbb{x}_n$ and velocity $\mathbb{v}_n$ is acted on by the sum of the Lorentz forces from all other particles of the same or other species

$$m_n \mathbb{x}_n = m_n \mathbb{v}_n = \sum_{k \neq n}^{N_s} q_k (\mathbb{E} + \mathbb{v}_k \times \mathbb{B}) \quad (3)$$

Note that the $\mathbb{x}_k, \mathbb{v}_k$ refer to the particles of various species s ; the species label is suppressed from here on to keep the notation simple. These equations are intractable since $N_s \sim 10^{20}$. A more tractable form is obtained by replacing the full particle distribution

function for N_s particles of various species, $F_s(\mathbf{x}_1, \mathbf{v}_1, \mathbf{x}_2, \mathbf{v}_2, \dots, \mathbf{x}_{N_s}, \mathbf{v}_{N_s})$, by a sequence of partial distribution functions, $f_s^{(n)}$, $n = 1, 2, \dots, N_s - 1$, obtained by integrating over the eliminated variables, so that,

$$f_s^{(n-1)}(\mathbf{x}_1, \mathbf{v}_1, \mathbf{x}_2, \mathbf{v}_2, \dots, \mathbf{x}_n, \mathbf{v}_n) \equiv \int \int f_s^{(n)}(\mathbf{x}_1, \mathbf{v}_1, \mathbf{x}_2, \mathbf{v}_2, \dots, \mathbf{x}_n, \mathbf{v}_n, \mathbf{x}_{n+1}, \mathbf{v}_{n+1}) d^3 \mathbf{x}_{n+1} d^3 \mathbf{v}_{n+1} \quad (4)$$

with $f_s^{(N_s-1)}(\mathbf{x}_1, \mathbf{v}_1, \mathbf{x}_2, \mathbf{v}_2, \dots, \mathbf{x}_{N_s}, \mathbf{v}_{N_s}) \equiv F_s(\mathbf{x}_1, \mathbf{v}_1, \mathbf{x}_2, \mathbf{v}_2, \dots, \mathbf{x}_{N_s}, \mathbf{v}_{N_s})$.

These are the so-called BBGKY equations. These contain similar information as $F_s(\mathbf{x}_1, \mathbf{v}_1, \mathbf{x}_2, \mathbf{v}_2, \dots, \mathbf{x}_{N_s}, \mathbf{v}_{N_s})$, namely the position and velocity of every particle of species s . The final so-called single particle distribution function is then,

$$f_s(\mathbf{x}, \mathbf{v}) \equiv f_s^{(0)}(\mathbf{x}_1, \mathbf{v}_1) = \int \int \int \dots F_s(\mathbf{x}_1, \mathbf{v}_1, \mathbf{x}_2, \mathbf{v}_2, \dots, \mathbf{x}_{N_s}, \mathbf{v}_{N_s}) \prod_{k=2}^{N_s} (d^3 \mathbf{x}_k d^3 \mathbf{v}_k) \quad (5)$$

Combining this with the equations of motion for the particles then yields the Boltzmann Equation for $f_s(\mathbf{x}, \mathbf{v})$ (Colonna, 2016):

$$\frac{\partial f_s}{\partial t} + \mathbf{v} \cdot \nabla_{\mathbf{x}} f_s + q_s/m_s [\mathbf{E}(\mathbf{x}, t) + \mathbf{v} \times \mathbf{B}(\mathbf{x}, t)] \cdot \nabla_{\mathbf{v}} f_s = C_s(f_a, f_\beta, f_\gamma, \dots, f_s, \dots, f_\zeta) \quad (6)$$

Here, $\nabla_{\mathbf{x}} f_s$ means $\nabla_{\mathbf{x}} f_s \equiv \left(\frac{\partial f_s}{\partial X} \quad \frac{\partial f_s}{\partial Y} \quad \frac{\partial f_s}{\partial Z} \right)^T$, and $\nabla_{\mathbf{v}} f_s \equiv \left(\frac{\partial f_s}{\partial V_x} \quad \frac{\partial f_s}{\partial V_y} \quad \frac{\partial f_s}{\partial V_z} \right)^T$ (the T represents the transpose). This coupled set of equations for various particle species ($\alpha, \beta, \dots, s, \dots, \zeta$) describes the evolution of the probability of finding a particle of species s at any given point $(\mathbf{x}, \mathbf{v})$ in phase space, at any given time due to electrodynamic and thermodynamic forces. The final term on the right side formally represents the effects of collisions between species, including those of the same species. For a collisionless plasma, $C_s = 0$, and the equation is called the Vlasov Equation (Colonna, 2016). Combined with Maxwell's Equations for the fields, the equations give a complete self-consistent account of the system of charged particles.

The MHD equations are obtained by taking velocity moments of the Boltzmann equations, for electrons and each ion species. For the velocity $\mathbf{v} \equiv (V_s^X \quad V_s^Y \quad V_s^Z)^T$, the velocity moments are defined by,

$$\langle V_s^\alpha V_s^\beta \dots V_s^\zeta \rangle_s \equiv \frac{\int V_s^\alpha V_s^\beta \dots V_s^\zeta f_s(\mathbf{x}, \mathbf{v}) d^3 \mathbf{v}}{\int f_s(\mathbf{x}, \mathbf{v}) d^3 \mathbf{v}} \quad (7)$$

for each of the coordinates, $\alpha, \beta, \dots, \zeta \in \{X, Y, Z\}$. We will use the notation V_s^α (with the s subscript) when designating the velocity moments. Without the subscript they refer to dummy integration variables. The first velocity moment (zeroth order) is just the number density defined as:

$$n_s(\mathbf{x}) = \langle n_s \rangle = \int f_s(\mathbf{x}, \mathbf{v}) d^3 \mathbf{v} \quad (8)$$

The second is the species single-fluid velocity, with three different moments corresponding to the three coordinate directions:

$$V_s^\alpha(\mathbf{x}) = \langle V_s^\alpha \rangle = \frac{\int V_s^\alpha f_s(\mathbf{x}, \mathbf{v}) d^3 \mathbf{v}}{\int f_s(\mathbf{x}, \mathbf{v}) d^3 \mathbf{v}} \quad (9)$$

The third describes the energy for each species defined as:

$$\frac{1}{2} n_s(\mathbf{x}) T_s^{\alpha, \beta}(\mathbf{x}) = \int \frac{1}{2} m_s (V_s^\alpha - V_s^\alpha(\mathbf{x})) (V_s^\beta - V_s^\beta(\mathbf{x})) f_s(\mathbf{x}, \mathbf{v}) d^3 \mathbf{v} \quad (10)$$

This is a symmetric tensor and the temperature for each species is then just found from

$$T_s(\mathbf{x}) = [T_s^{x,x}(\mathbf{x}) + T_s^{y,y}(\mathbf{x}) + T_s^{z,z}(\mathbf{x})]/3 \quad (11)$$

$$T_s^{\alpha, \alpha}(\mathbf{x}) = \langle m_s (V_s^\alpha - V_s^\alpha(\mathbf{x}))^2 \rangle_s \quad (12)$$

A pressure tensor for each species can also be defined. This is a symmetric tensor, $\mathbb{P}$, with components

$$P_s^{\alpha, \beta}(\mathbf{x}) \equiv n_s(\mathbf{x}) T_s^{\alpha, \beta}(\mathbf{x}) = \langle m_s (V_s^\alpha - V_s^\alpha(\mathbf{x})) (V_s^\beta - V_s^\beta(\mathbf{x})) \rangle_s \int f_s(\mathbf{x}, \mathbf{v}) d^3 \mathbf{v} \quad (13)$$

The tensor $\mathbb{T}$ and the temperature $T_s(\mathbf{x})$ are in units of energy so $T_s(\mathbf{x})$ is really k times the temperature in Kelvins, where k is the Boltzmann's constant.

The full set of moment equations coupled with Maxwell's equations provides a complete formal description of the system. The first two moments provide a set of equations that essentially describe mass and momentum conservation for each species. For a plasma of just two species, ions and electron, one can recombine these first moment equations into a single-fluid form by replacing each pair of species equations by their weighted sum and difference to eliminate $\mathbf{v}_i$ and $\mathbf{v}_e$ by the fluid velocity $\mathbf{v}$, which is the common velocity of the two species,

$$\mathbf{v} \equiv (m_i n_i \mathbf{v}_i + m_e n_e \mathbf{v}_e) / (m_i n_i + m_e n_e) \quad (14)$$

and the velocity difference represented by the current density,

$$\mathbf{j} = (q_i n_i \mathbf{v}_i + q_e n_e \mathbf{v}_e) \quad (15)$$

The total mass density is,

$$\rho_m = (m_i n_i + m_e n_e) \quad (16)$$

and the total (tensor) pressure is,

$$\mathbb{P} = \mathbb{P}_i + \mathbb{P}_e \quad (17)$$

Then, the zeroth-order moment becomes the particle conservation equation;

$$\frac{\partial \rho_m}{\partial t} + \nabla \cdot (\rho_m \mathbf{v}) = 0 \quad (18)$$

familiar from conventional fluid theory. The first order moment equations become a simple force balance momentum conservation equation, which can be written as the vector equation,

$$\rho_m \left(\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{v} \right) + \nabla \cdot \mathbb{P} - (\mathbf{j} \times \mathbb{B}) = 0 \quad (19)$$

The first two terms on the left represent the inertia. The other two terms are the pressure force and the electromagnetic force. In equilibrium, with $\mathbf{v} = 0$, the pressure and electromagnetic forces are balanced. While at this point the model is two-fluid, these equations are in a single-fluid form.

In general, higher velocity moments from higher order equations are required in each new equation, and at second order, the situation becomes significantly more complicated. The individual electron and ion terms cannot be completely eliminated without additional approximations. At second order, one obtains two equations. One is effectively a generalized Ohm's Law

$$\mathbb{E} + \mathbf{v} \times \mathbb{B} = \eta \mathbf{j} + \mathbb{R} \quad (20)$$

$$\mathbb{R} = \left(\frac{1}{q_e n_e} \right) \nabla \cdot \mathbb{P}_i + \left(\frac{\Delta n_e}{n_e} \right) \mathbb{E} + \left(\frac{m_i}{q_i} \right) \left(\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{v} \right) + \left(\frac{m_e}{q_e} \right) \left(\frac{\partial (\mathbf{v}_i - \mathbf{v}_e)}{\partial t} + (\mathbf{v} \cdot \nabla) (\mathbf{v}_i - \mathbf{v}_e) \right) \quad (21)$$

$\mathbb{R}$ contains the remaining unbalanced two-fluid terms, including the Hall effect. Most are small and can normally be neglected. The other is a tensor equation for the evolution of the pressure tensor, $\mathbb{P}$ given below.

Truncating the separate ion and electron equations at this order, then one obtains the full set of MHD equations:

$$\frac{\partial \rho_m}{\partial t} + \nabla \cdot (\rho_m \mathbf{v}) = 0 \quad (22)$$

$$\frac{\partial \sigma}{\partial t} + \nabla \cdot \mathbf{j} = 0 \quad (23)$$

$$\frac{\partial \mathbb{B}}{\partial t} + \nabla \times (\mathbb{E}) = 0 \quad (24)$$

$$-\frac{1}{c^2} \frac{\partial \mathbb{E}}{\partial t} + \nabla \times (\mathbb{B}) = \mu_0 \mathbf{j} \quad (25)$$

$$\nabla \cdot \mathbb{B} = 0 \quad (26)$$

$$\nabla \cdot \mathbb{E} = \varepsilon_0^{-1} \sigma \quad (27)$$

$$\rho_m \left(\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla) \mathbf{v} \right) = \sigma \mathbb{E} + \mathbf{j} \times \mathbb{B} - \nabla \cdot \mathbb{P} \quad (28)$$

$$\mathbb{E} + \mathbf{v} \times \mathbb{B} = \eta \mathbf{j} + \mathbb{R} \quad (29)$$

$$\frac{\partial}{\partial t} \mathbb{P} + (\mathbf{v} \cdot \nabla) \mathbb{P} = \nabla \cdot \mathbb{Q} + \mathbb{S} \quad (30)$$

with $\mathbb{Q}$ representing a (generalized) stress-energy tensor flux and $\mathbb{S}$ a generalized dissipation. In this general form, MHD is a full two-fluid theory but it is not closed. The generalized stress-energy tensor and dissipation in Eq. (30) are obtained formally from the higher order truncated terms, but most closures involve specifying them independently instead, along with several simplifying assumptions for $\mathbb{R}$.

Various closure schemes are possible and these lead to different versions of MHD. The most important approximation is the Darwin Approximation;

$$\frac{1}{c^2} \frac{\partial \mathbb{E}}{\partial t} \ll \nabla \times \mathbb{B} \sim \mu_0 \mathbf{j} \quad (31)$$

which essentially eliminates propagating purely electromagnetic waves from the system. This is almost always a good approximation and is consistent with the ignoring of relativistic dynamics. Of the various simplified MHD models, the Darwin approximation is the most valid and is almost always assumed. With the Darwin approximation, the remaining equations are usually referred to as the “Two-Fluid MHD Equations”, or sometimes, with an appropriate closure, as the Extended MHD Equations.

The remaining common assumptions such as no resistivity $\eta = 0$, isotropic pressure $p_\perp = p_\parallel$, or $T_e = T_i$ are variously valid under different circumstances. These are usually based on approximations from fluid dynamics and thermodynamics. For example, relations between $\mathbb{P}$ and the mass density for each species, or an assumption for off-diagonal pressure (stress) terms in $\mathbb{P}$ are often used. Separate leftover electron terms of the full two-fluid model (Hall and ∇p_e terms) are commonly dropped as small, leaving simpler single-fluid equations. These are usually referred to as “the MHD Equations” or the “Single-Fluid MHD” equations. Assuming a scalar pressure, one obtains a much simpler system with relatively simple closure options. An alternative is the Chew-Goldberger-Low CGL model (Hunana et al., 2019) which allows for pressure anisotropy $P_\perp \neq P_\parallel$. Finally, if the resistivity is also ignored, $\eta \mathbf{j} \ll \mathbf{v} \times \mathbb{B} \sim \mathbb{E}$, then $\mathbb{E} + \mathbf{v} \times \mathbb{B} \sim 0$ and

$$\frac{\partial \mathbb{B}}{\partial t} = \nabla \times (\mathbf{v} \times \mathbb{B}) \quad (32)$$

implies that the fluid moves with the fields; there is no slippage between them. This condition is called the frozen flux theorem and the resulting MHD model is commonly referred to as ‘ideal MHD’. In addition, since the equations are physically intuitive, representing various conservation laws, ad-hoc phenomenological terms can be included as closures to model effects that have been eliminated, for example, fast-particle drive effects, or neoclassical effects.

Toroidal equilibrium

The shape of the equilibrium magnetic surfaces plays an important role in determining its stability and performance. The ideal MHD momentum balance Eq. (19) provides a comprehensive physics constraint to compute and optimize the required external poloidal magnetic-field coil set and its currents necessary to produce a target plasma boundary shape (defined as the largest closed magnetic surface enclosed by the surrounding limiter and vacuum vessel), and the diversion of the external magnetic-field lines to direct the particle and heat flux to the divertor collecting plate.

At equilibrium and in the absence of plasma flow and pressure anisotropy, the MHD equilibrium Eq. (19) and Ampere’s law Eq. (25) become

$$\nabla P = \mathbf{j} \times \mathbb{B} \quad (33)$$

$$\nabla \times \mathbb{B} = \mu_0 \mathbf{j} \quad (34)$$

It follows from Eqs. (33) and (34) that the confining magnetic force is in the direction perpendicular to the magnetic field lines. At equilibrium, the pressure must be constant on a magnetic flux surface $P = P(\psi)$ and the plasma current density $\mathbf{j}$ flows along the surface.

In a toroidal axisymmetric device such as tokamak, a set of 2D nested magnetic surfaces is formed using a toroidal-field and a poloidal-field coil set. A dedicated Ohmic-coil set is also sometimes employed to drive the toroidal current flowing within the plasma to ease control as in the DIII-D (Luxon, 2002) and ASDEX Upgrade (Gruber and ASDEX Upgrade Project Group, 1986) tokamaks, rather than combining the functionality into a single set of poloidal-field coils for both shaping and driving Ohmic current as in more recent superconducting long-pulse tokamak devices such as EAST (Wan et al., 2006), KSTAR (Lee et al., 1999), JT-60SA (Kamada et al., 2011), and ITER (<https://www.iter.org/>) (ITER Physics Basis Editors, 1999a). In the presence of toroidal asymmetry, magnetic islands and stochastic regions can form, degrading the plasma confinement and making it more susceptible to MHD instabilities.

Axisymmetric 2D Grad-Shafranov equilibrium

In an axisymmetric toroidal device such as a tokamak, Eqs. (33) and (34) can be combined to yield a 2D elliptic equilibrium equation, the Grad-Shafranov (GS) equation (Grad and Rubin, 1956; Shafranov, 1958), by considering force balance in the direction perpendicular to the magnetic field $\mathbb{B}$ and using a cylindrical (R, φ, Z) coordinate system centered at the symmetric axis and dropping the toroidal φ -dependent terms

$$\Delta^* \psi = -\mu_0 R j_\varphi(R, \psi) \quad (35)$$

$$j_\varphi = RP'(\psi) + \frac{\mu_0 FF'(\psi)}{4\pi^2 R} \quad (36)$$

Here, the operator $\Delta^* = R^2 \nabla \cdot (\nabla/R^2)$. The magnetic field can be conveniently represented as

$$\mathbb{B} = \frac{\mu_0 F(\psi)}{2\pi} \nabla \varphi + \nabla \psi \times \nabla \varphi \quad (37)$$

The first term in Eq. (37) represents the toroidal component of $\mathbb{B}$, whereas the second term represents the poloidal component.

The GS equilibrium, Eq. (35), is based on the cylindrical (R, φ, Z) coordinate system. An alternative coordinate system is the inverse magnetic-flux coordinate system (ρ, θ, φ) using a flux-surface label $\rho(\psi)$ and a poloidal angle θ as independent variables (Boozer, 2005). The GS Eq. (35) can then be transformed to become the inverse GS equation for $R(\rho, \theta)$ or $Z(\rho, \theta)$ (Lao et al., 1981). Since the pressure $P(\psi)$ is constant on a flux surface, the inverse magnetic-flux coordinate system (ρ, θ, φ) provides a particularly convenient coordinate system to study plasma equilibrium, transport, and stability physics. In the case of a diverted plasma, the use of the magnetic-flux coordinate system is restricted to the nested magnetic-surface region within the plasma to avoid the singularity at the separatrix surface that appears in the Jacobian for transformation from the (R, φ, Z) to the (ρ, θ, φ) coordinate system.

Eq. (35) represents a differential form of the GS equation. It acts as a constraint linking the derivatives of ψ to the current sources. Given two stream functions describing the toroidal current density source such as $P(\psi)$ and $F(\psi)$ as shown in Eq. (36) and appropriate boundary conditions, Eq. (35) can be solved for the poloidal flux function ψ . Two other forms of the GS Eq. (35) useful for finding equilibrium solutions are the integral and the variational Lagrangian forms (Grad and Rubin, 1956; Lao et al., 1981, 1985a, 2005).

$$\psi(\mathbf{x}) = \sum_j G_\psi(\mathbf{x}, \mathbf{x}_{ej}) I_{ej} + \int_{\Omega_B} G_\psi(\mathbf{x}, \mathbf{x}') j_\varphi[\mathbf{x}', \psi(\mathbf{x}')] dR' dZ' \quad (38)$$

$$W = \int_{\Omega_B} \left(\frac{B_p^2}{2\mu_0} - \frac{B_T^2}{2\mu_0} - P \right) d\Omega \quad (39)$$

Here $G_\psi(\mathbf{x}, \mathbf{x}')$ is the Green induction function relating $\psi(\mathbf{x})$ to the current source at $\mathbf{x}'$. The variational Lagrangian form Eq. (39) provides a systematic means to transform the solution $\psi(R, Z)$ of the 2D GS equilibrium Eq. (35) into a series of 1D moment equations for the Fourier amplitudes of $R(\rho, \theta)$ or $Z(\rho, \theta)$ (Lao et al., 1981). The 2D variational moment approach has been successfully generalized to provide a robust and efficient method to find equilibrium solutions in 3D toroidal geometry with nested magnetic surfaces (Bhattacharjee et al., 1983; Hirshman and Whitson, 1983; Lao et al., 1985c).

Analytical solutions exist when the current source Eq. (36) has simple forms (Solov'ev, 1968; Srinivasan et al., 2010) or when the magnetic surface has simple circular geometry (Lao et al., 1981). In general, the GS Eq. (35) or its integral or variation form Eqs. (38) or (39) must be solved numerically (Johnson et al., 1979; Takeda and Tokuda, 1991). Many tools are available to numerically search and compute the equilibrium solutions given two stream functions describing the toroidal current density source and appropriate boundary conditions (Lao, 1984; Lao et al., 1985a, 2005; Haney et al., 1995; Ivanov et al., 2009). One class of applications is to find a solution that best matches a specified target plasma boundary given the two stream functions, a set of external poloidal-field coils, and a surrounding limiter. An example of a DIII-D equilibrium computed with the EFIT code (Lao et al., 1985a, 2005) is given in Fig. 2. Another class of applications is to find a solution that best matches a specified target plasma boundary but with the

Fig. 2 Poloidal cross-section of a DIII-D tokamak lower single-null equilibrium computed using the EFIT equilibrium code. Also shown is a photo of the DIII-D tokamak with its toroidal- and poloidal-field coils.

two stream functions self-consistently computed based on the plasma transport properties (Grad and Hogan, 1970; Hirshman and Jardin, 1979; Meneghini et al., 2016).

Equilibrium reconstruction

Reconstruction of experimental MHD equilibria is fundamental to tokamak research and operation and is an important part of fusion data analysis and plasma control. Equilibrium reconstruction provides essential magnetic geometry and current and pressure profile information necessary to support tokamak operation and data analysis, and has contributed to several major physics discoveries, such as the experimental validation of theoretically predicted β stability limits (Strait et al., 1994) and the negative central-shear operating regime (Levinton et al., 1995; Strait et al., 1995).

A particularly important application of the GS Eq. (35) is to reconstruct the experimental plasma equilibrium from various available measurements such as external magnetic and internal current and kinetic profile diagnostics (Lao et al., 1985a, 1990, 2005). The amount of plasma information that can be reconstructed increases with the availability of the measurements. External magnetic measurements alone can only yield the plasma boundary shape and global plasma pressure and current profile parameters, such as poloidal β , $\beta_P = \int_0^{\Omega_B} P d\Omega / (\Omega_B B_{PA}^2 / 2\mu_0)$, and internal inductance of the plasma current density profile $\mathcal{L}_i = \int_0^{\Omega_B} B_P^2 d\Omega / (\Omega_B B_{PA}^2)$, and $B_{PA} = \oint \psi_B B_P d\ell_p / \oint \psi_B d\ell_p$ is the average poloidal magnetic field along the plasma boundary surface (Lao et al., 1985b; Braams, 1991). For critical applications such as analysis and control of MHD instabilities that require detailed pressure and current profile information, accurate full equilibrium reconstruction with kinetic and internal current profiles in addition to external magnetic measurements is required, as well as high spatial-resolution and tightly converged equilibrium solutions (Lao et al., 1990; Ren et al., 2011). Plasma control also imposes a stringent requirement on the equilibrium reconstruction computational speed. Various efficient numerical algorithms and high-performance computation technology have been developed and employed to reconstruct tokamak experimental equilibria in real time to provide the information necessary for plasma control (Ferron et al., 1998; Moret et al., 2015; Ramp et al., 2017; Huang et al., 2020).

MHD stability

Introduction and overview

In principle, the full nonlinear (Extended) MHD model should be reliable under the conditions that the plasma be quasi-neutral and that the length and time scales be long: specifically that the length scales be of the order of the plasma minor radius, and much larger than microscopic scales like the Larmor radius, and that the time scales are much slower than Alfvénic times.

Experimental diagnostic capabilities have been developed to the point where detailed predictions from MHD theory can be productively tested. As discussed in the previous Equilibrium Reconstruction Section, the key to this development has been the progress in reconstructing equilibria obeying MHD force balance and consistent with experimentally measured kinetic profiles (Lao et al., 1990). The linear MHD stability predictions using high quality discharge full equilibrium reconstructions have been thoroughly tested against observations for the principal limiting phenomena and MHD generally predicts ideal current and pressure limits well (Turnbull et al., 2002; Turnbull et al., 2005). In particular, global pressure driven instabilities are predicted to be unstable when the plasma β_T exceeds a value typically of a few percent. β_T measures the amount of thermal energy the plasma can hold for a given magnetic field strength.

A series of numerical ideal MHD stability calculations in the mid 1980s discovered that the limiting β_T obeys a scaling known as the Troyon limit, given originally as

$$\beta_T \leq \beta_{TROY} \equiv C_T (\mu_0 I_P) / (a B_T) \quad (40)$$

where $C_T = 2.8$ if I_P is in Amperes and B_T is in Tesla (Troyon et al., 1984). This was immediately confirmed by experiments on a number of tokamaks (Stambaugh et al., 1984) and is commonly referred to as the Troyon beta limit. (This has been a point of confusion; the difference between C_T and β_N^{max} has erroneously been claimed to be a discrepancy.)

$$\beta_T \leq \beta_N^{max} I_P(\text{MA}) / (a B_T) \quad (41)$$

with $\beta_N^{max} = 3.5$. In subsequent years, the Troyon limit scaling has been modified to account for the major profile and shaping effects. The most recent version replaces the constant $\beta_N^{max} = 3.5$ by

$$\beta_N^{max} = k_\beta \mathcal{L}_i \quad (42)$$

where $\mathcal{L}_i$ is the internal inductance of the current density profile and k_β varies from 2.5 for conventional elongated, single null, low-triangularity plasmas to $k_\beta = 4$ for high-triangularity double-null plasmas. In spherical tokamaks, the value can be much higher (Sabbagh et al., 2006). The $\mathcal{L}_i$ dependence is consistent with results from an analytical ideal ballooning β -limit study (Lao et al., 1992), and a numerical study of the $n = 1$ ideal kink β -limit (Howl et al., 1992).

Ideal linear MHD stability and energy principle

In the ideal case, the equations have special properties that lead to efficient numerical calculation schemes, the most important of which is the ideal MHD energy principle for linear stability against small departures from equilibrium. Assuming an ideal equilibrium without flows $\mathbf{v}_0 = 0$ and a scalar pressure, the dynamic quantities can be linearized in the small perturbation: $P(\mathbf{x}, t) = P_0(\mathbf{x}) + P_1(\mathbf{x}, t)$; $\mathbf{j}(\mathbf{x}, t) = \mathbf{j}_0(\mathbf{x}) + \mathbf{j}_1(\mathbf{x}, t)$; and $\mathbf{B}(\mathbf{x}, t) = \mathbf{B}_0(\mathbf{x}) + \mathbf{B}_1(\mathbf{x}, t)$, with each perturbed quantity assumed much smaller

than the equilibrium term, yielding an equation for the equilibrium and an equation describing the linear first-order force balance

$$\nabla P_0 = \mathbf{j}_0 \times \mathbb{B}_0 = \left(\frac{1}{\mu_0} \right) (\nabla \times \mathbb{B}_0) \times \mathbb{B}_0 \quad (43)$$

$$\rho_0 \left(\frac{\partial \mathbf{v}_1}{\partial t} \right) + \nabla P_1 = \mathbf{j}_1 \times \mathbb{B}_0 + \mathbf{j}_0 \times \mathbb{B}_1 \quad (44)$$

From here, in order to simplify the subsequent notation, we write $\mathbb{B} = \mathbb{B}_0$, and $\delta \mathbb{B}_p = \mathbb{B}_1$ and similarly for $\mathbf{j} = \mathbf{j}_0$ and $\delta \mathbf{j}_p = \mathbf{j}_1$. The ideal MHD frozen flux relation becomes a relation between the perturbed field $\delta \mathbb{B}_p$ and fluid displacement ξ ;

$$\delta \mathbb{B}_p = \nabla \times (\xi \times \mathbb{B}) \quad (45)$$

$\xi \times \mathbb{B}$ is the perturbed vector potential. After some algebra, one finds an equation of motion for the small displacement $\xi(\mathbf{x}, t)$ and perturbed velocity $\mathbf{v}_1(\mathbf{x}, t) \equiv \xi(\mathbf{x}, t)$;

$$\rho_0 \ddot{\xi}(\mathbf{x}, t) = \mathcal{F}(\xi(\mathbf{x}, t)) \quad (46)$$

with $\mathcal{F}(\xi)$ a linear operator on ξ : $\mathcal{F}(\xi) \equiv \mathbb{F}(\mathbf{x}) \cdot \xi$;

$$\mathcal{F}(\xi) \equiv \mathbb{F}(\mathbf{x}) \cdot \xi \equiv \left(\frac{1}{\mu_0} \right) [((\nabla \times \delta \mathbb{B}_p) \times \mathbb{B}) + ((\nabla \times \mathbb{B}) \times \delta \mathbb{B}_p)] + \nabla(\xi \cdot \nabla P + \Gamma P \nabla \cdot \xi) \quad (47)$$

$\mathbb{F}(\mathbf{x})$ is known as the (linearized) force operator and Γ is the adiabatic index. The solutions to $\xi(\mathbf{x}, t)$ must be temporally exponential, $\xi(\mathbf{x}, t) \equiv \xi(\mathbf{x}) e^{i\omega t}$, leading to an eigenvalue equation for the spatial variation of the displacement, $\xi(\mathbf{x})$ and its eigenvalue ω^2 ;

$$\rho_0^{-1} \mathbb{F}(\mathbf{x}) \cdot \xi(\mathbf{x}) = -\omega^2 \xi(\mathbf{x}) \quad (48)$$

Note that $\xi^\dagger \cdot \mathbb{F} \cdot \xi = \mathcal{F}(\xi) \cdot \xi^\dagger$ represents the work done by the infinitesimal force $\mathcal{F}(\xi)$ against the infinitesimal displacement ξ .

Boundary conditions need to be applied by specifying the displacement of the plasma boundary. For a plasma surrounded by a vacuum region and possibly a conducting wall outside, this is not explicitly known. Boundary conditions can be set, however, by solving simultaneously for $\delta \mathbb{B}_p$ and $\xi(\mathbf{x})$ and the ideal frozen flux relation linking them, and solving for the perturbed vacuum field, $\delta \mathbb{B}_v$, in the annulus between the plasma and the wall.

$$\nabla \times \delta \mathbb{B}_v = \nabla \cdot \mathbb{B}_v = 0 \quad (49)$$

which is most easily solved in terms of a magnetic potential, $\delta \mathbb{B}_v = \nabla \Phi$;

$$\nabla^2 \Phi = 0 \quad (50)$$

An appropriate magnetic boundary condition for a conducting wall, or for a wall at infinity can then be applied;

$$\hat{\mathbf{m}} \cdot \nabla \Phi|_w = 0 \quad (51)$$

The perturbed fields must then be matched across the plasma boundary. This condition is complicated since they must be matched across the perturbed boundary;

$$\hat{\mathbf{m}} \cdot \delta \mathbb{B}_p|_{pv} = \hat{\mathbf{m}} \cdot \nabla \Phi|_{pv} \quad (52)$$

The matrix $\mathbb{F}(\mathbf{x})$ is self-adjoint (or Hermitian); $\xi^\dagger \cdot \mathbb{F} \cdot \xi = \xi \cdot \mathbb{F} \cdot \xi^\dagger$. The Hermitian property provides a number of computational advantages (Bernstein et al., 1957). Notably, the eigenvalues $-\omega^2$ are purely real. Thus, the solutions are either purely growing or damped, or are purely oscillatory. The Hermitian property also means one can conveniently reformulate the dynamic problem as a variational problem. Pre-multiplying the equation of motion in the plasma by the adjoint, $\xi^\dagger$, and integrating over all space, one obtains a variational principle (Bernstein et al., 1957). Application of physically relevant boundary conditions in the variational formulation is non-trivial. This is solved by deriving an extended form of the energy principle in which conditions across the plasma vacuum interface, Eq. (52) above, is automatically satisfied by the variational solutions. Formulated as a statement of conservation of energy, the extended form of the energy principle is;

$$\delta W - \omega^2 \delta K = 0 \quad (53)$$

$$\delta W(\xi, \xi^\dagger, \delta \mathbb{B}_v, \delta \mathbb{B}_v^\dagger) \equiv \delta W_p(\xi, \xi^\dagger) + \delta W_v(\delta \mathbb{B}_v, \delta \mathbb{B}_v^\dagger) \quad (54)$$

$$\delta K(\xi, \xi^\dagger) \equiv \frac{1}{2} \int_p \rho_0(\mathbf{x}) (\xi^\dagger \cdot \xi) d^3 \mathbf{x} \quad (55)$$

$$\delta W_p(\xi, \xi^\dagger) \equiv \frac{1}{2\mu_0} \int_p (\xi^\dagger \cdot \mathbb{F}(\mathbf{x}) \cdot \xi) d^3 \mathbf{x} \quad (56)$$

$$\delta W_v(\delta \mathbb{B}_v, \delta \mathbb{B}_v^\dagger) \equiv \frac{1}{2\mu_0} \int_p (\delta \mathbb{B}_v^\dagger \cdot \delta \mathbb{B}_v) d^3\mathbb{x} \quad (57)$$

δW_v is the vacuum energy contribution from perturbing the plasma boundary. The integrals δK and δW_p are over the plasma volume, and δW_v is over the annular vacuum region. δW represents the total potential energy and δK is the kinetic energy of the perturbing motion. Then δW_p is the plasma potential energy. The energy principle states that if a physically permissible displacement ξ can be found such that $\delta W(\xi, \xi^\dagger) > 0$, then the plasma is unstable. The energy principle can therefore be used in a trial function approach. Finding a physically permissible trial function, ξ_0 , for which $\delta W(\xi_0, \xi_0^\dagger) > 0$, thus guarantees instability. Note, however, that the trial function is not necessarily the instability that would appear. The variational principle only implies that this or another more unstable mode will be destabilized.

Substituting for $\mathbb{F}(\mathbb{x})$, the Extended MHD Principle potential energy becomes after some algebra:

$$\delta W_p = \frac{1}{2} \iiint \left[\frac{\delta \mathbb{B}_p^2}{\mu_0} - \xi_\perp^* \cdot (\hat{\mathbb{j}} \times \delta \mathbb{B}_p) + (\xi_\perp \cdot \nabla P) \nabla \cdot \xi_\perp^* + \Gamma P |\nabla \cdot \xi|^2 \right] d^3\mathbb{x} \quad (58)$$

The integral in δW_p is over the plasma and the condition applied is simply that $\delta \mathbb{B}_p = \delta \mathbb{B}_v$ at the plasma vacuum interface. The terms in δW_p can be interpreted physically. The first term in δW_p represents the energy required to bend the field lines. It is always stabilizing—it takes energy input to create this; it is the energy in the perturbed field. The second term, $\xi_\perp^* \cdot (\hat{\mathbb{j}} \times \delta \mathbb{B}_p)$ is the destabilization from the current density. The third term is the pressure drive through $\xi_\perp \cdot \nabla P$. The final term represents the energy associated with plasma compression. δW_p can be rewritten in the alternative form;

$$\delta W_p = \frac{1}{2} \iiint \left[\delta \mathbb{B}_\perp^2 / \mu_0 + \left(\frac{\mathbb{B}^2}{\mu_0} \right) |\nabla \cdot \xi_\perp + 2\xi_\perp \cdot \kappa|^2 - \left| \frac{\hat{\mathbb{j}}_\parallel}{\mathbb{B}} \right| (\xi_\perp^* \times \mathbb{B}) \cdot \delta \mathbb{B}_\perp - 2(\xi_\perp \cdot \nabla P)(\xi_\perp^* \cdot \kappa) + \Gamma P |\nabla \cdot \xi|^2 \right] d^3\mathbb{x} \quad (59)$$

This shows more clearly the physical meaning of the terms. The first represents the energy required to bend field lines. The second corresponds to the energy involved in compression of the field. The third and fourth terms are respectively the destabilization from current driven modes, proportional to $|\hat{\mathbb{j}}_\parallel / \mathbb{B}|$ and ∇P , respectively. The last term, again is the energy from the fluid compression.

The MHD model works extremely well in most situations. In particular, the plasma cross section shape is easily included, at least in numerical calculations as boundary conditions, thus fully capturing the most basic zeroth order effect. MHD is now recognized as an indispensable guide to any design efforts.

Pressure effects

Plasma equilibrium pressure is mostly destabilizing for MHD modes. Associated with the destabilization is the free energy contained in the pressure gradient. This is evident from the ideal MHD energy principle, where the term $-(\xi_\perp \cdot \nabla P)(\xi_\perp^* \cdot \kappa)$ from Eq. (59), integrated over the plasma volume, can be negative and thus provides destabilization. This is the drive term for the ballooning and interchange instabilities. The interchange instability involves a Rayleigh-Taylor interchange of two neighboring field lines. The ballooning mode is then a local interchange of a section of the field line in a sheared field; essentially the field line under higher pressure ‘balloons’ through the lower pressure field lines where the local shear is weak. The pressure gradient triggers MHD instabilities when it exceeds certain critical values. Below are important examples. The pressure driven ideal external kink mode (EK) becomes unstable when the normalized beta exceeds the Troyon limit (Troyon et al., 1984). Being a global instability, the EK mode is not sensitive to the local pressure gradient, but is still driven by the “global” pressure gradient which is often measured by the so-called pressure peaking factor. The ideal IK mode becomes unstable when the plasma pressure (often measured in poloidal beta value β_p) exceeds the Bussac limit (Bussac et al., 1975). The infernal mode becomes unstable when β_p exceeds a critical value linearly scaling with Δq , which measures proximity of the global or local q_{min} value to a rational number. The neoclassical tearing mode (NTM), which is generally a non-linear MHD mode, requires a seed island of finite size which scales with β_p . Besides these direct drives, the equilibrium plasma pressure gradient also induces bootstrap current which in turn can drive MHD instabilities. Bootstrap current is a toroidal current driven by non-ideal effects due to the temperature and density gradients. It arises from trapped particle effects.

The plasma equilibrium pressure gradient can also be stabilizing for certain MHD modes. The most prominent example is the second ballooning stability regime, which arises from the large Shafranov-shift induced field-line compressing at the low-field side of the plasma, where the ballooning mode is typically located due to unfavorable magnetic curvature. In a tokamak plasma, the interchange index D_R , which scales with the local equilibrium pressure gradient at the mode rational surface, appears also in the tearing mode stability criterion (Glasser et al., 1975). This can be negative, as a result of the average curvature effect, resulting in stabilization of the tearing mode.

Current effects

Plasma equilibrium current is often a major driving force for MHD instabilities in a tokamak plasma. Being a large quantity in a tokamak, the plasma current can easily provide free energy if the current density profile is not well optimized. (We note that large plasma current offers good energy confinement in tokamak plasmas.). In terms of the MHD energy principle, the current-drive term is associated with the plasma volume integral of $-\frac{1}{2} |\hat{\mathbb{j}}_\parallel / \mathbb{B}| (\xi_\perp^* \times \mathbb{B}) \cdot \delta \mathbb{B}_\perp$ term from Eq. (59), i.e., the primary drive is due to the equilibrium parallel current $j_\parallel$. In MHD theory, the current drive is often manifested in the value of safety factor q , which is roughly

inversely proportional to the toroidal current integrated over a plasma volume enclosed by the given magnetic flux surface, as shown in Eq. (1). Therefore, many current driven MHD instabilities are controlled by the safety factor q . Below is a list of important MHD modes that are at least partly driven by the plasma current.

The most important current driven MHD mode is the $n = 1$ ideal EK, which becomes unstable when the edge safety factor drops below 2 in a tokamak plasma. The edge safety factor is measured in terms of the edge q_s for a limiter plasma, and is often measured in terms of q_{95} (q at normalized $\psi = 0.95$) for a divertor plasma. This results in the ideal EK instability which usually leads to plasma disruption. It is difficult to overcome this stability limit but partial success has been achieved in recent experiments via active control of this instability (Hanson et al., 2014; Piovesan et al., 2014). A less severe, but often observed current driven instability is the IK mode, which can be unstable when the core safety factor q drops below 1. This is often manifested as the sawtooth instability in experiments. At higher values of edge q close to a low order rational number, the edge localized kink-peeling mode can be unstable. Similarly, if the safety factor profile is non-monotonic along the plasma minor radius and q_{min} (the minimum q value) is close to a low order rational number, an unstable infernal mode can occur. (More precisely, a finite pressure gradient is also required to drive the instability. The infernal mode can therefore be regarded as a MHD instability driven by both plasma current and pressure.) Finally, the plasma current density profile, alone or in combination with the plasma pressure, determines the tearing-mode index Δ' (Glasser et al., 1975) from the ideal region, which directly affects the tearing mode instability. The plasma current density profile is also directly related to the magnetic shear. A strong (positive) magnetic shear is generally stabilizing for most of MHD modes. Negative magnetic shear which occurs in plasmas with non-monotonic q -profiles can stabilize the tearing mode.

Resistivity effects

Many ideal MHD instabilities have resistive counterparts. Typically, the most interesting situation is that the ideal branch is stable within a certain parameter range, but taking into account the finite plasma resistivity qualitatively changes the picture by rendering the mode unstable, resulting in a resistive instability. Prominent examples are the tearing mode, the resistive interchange, the resistive internal kink, and the resistive external kink mode. Of course, the plasma resistivity also modifies (mostly enhances) the growth rate of an unstable ideal counterpart and the degree depends on the corresponding ideal instability. For instance, the plasma resistivity typically has very minor effect on an ideal external kink mode which grows at the Alfvénic time scale.

Within the MHD theory, the key physics associated with the plasma resistivity is that the ideal frozen-flux constraint is not valid. The plasma displacement and the magnetic field perturbation can evolve separately. As a consequence, the magnetic topology is allowed to change near a mode rational surface, resulting in magnetic islands, thus creating additional freedom for the plasma motion and for the perturbation to grow. This is the fundamental mechanism for the destabilization of the resistive instability when the ideal counterpart is stable.

On the other hand, there are also cases where the plasma resistivity plays a stabilizing role by dissipating free MHD energy via the resistive layer. One example is the fishbone instability, which is stabilized by finite plasma resistivity (Biglari and Chen, 1986; Wu et al., 2018). Another example is the resistive-plasma resistive-wall mode (RPRWM), where the global ideal MHD instability RWM couples to the tearing mode localized near a rational surface. The favorable average curvature stabilization of the tearing component within the resistive layer helps to stabilize the RPRWM (He et al., 2014). This mechanism applies when the coupling between the ideal and the resistive components is strong.

The TM is probably the most studied resistive instability (Glasser et al., 1975; Hegna and Callen, 1994). Both linear and non-linear theories are well developed. Several approaches have been established to study resistive instabilities, including the asymptotic matching, typically employed in analytic theory but also be useful in numerical codes.

Effects of plasma toroidal flow

Equilibrium toroidal plasma flow, as well as flow shear can affect MHD instabilities. (Plasma poloidal flow can in principle also affect MHD instabilities such as the RWM, but this is often not a significant concern, because poloidal flow is often slow in a tokamak plasma due to neoclassical damping.) Parallel plasma flow (along magnetic field lines) typically does not have significant effect on the MHD instability (Xia et al., 2019). The stabilization mechanism varies depending on the type of MHD mode. First, for the effect purely from the flow amplitude, imagine a flow that is uniform along the plasma minor radius. For many localized MHD modes, this uniform flow merely introduces a Doppler shift to the mode frequency (a change of reference from the laboratory frame to the rotating plasma frame), without modifying the mode growth rate. This may, however, be different for more global (in terms of plasma displacement) MHD modes. Two important examples are the RWM and the IK modes. The RWM does not rotate with the plasma and therefore is subject to continuum wave damping due to plasma flow. The IK is subject to a gyroscopic stabilization when the Mach number reaches a value comparable to the inverse aspect ratio.

On the other hand, flow shear typically destabilizes macroscopic MHD modes, unlike microscopic instabilities for which flow shear often plays a stabilizing role. The fundamental destabilization physics originates from the Kelvin-Helmholtz mechanism, where two adjacent fluid elements flowing at different velocities develop an unstable motion that eventually leads to turbulent flow. Flow shear destabilization has been found for many MHD modes, such as the RWM and the IK.

On the other hand, flow shear may help to stabilize certain MHD modes. One example is the observed 3/2 NTM island reduction from plasma flow in DIII-D experiments (La Haye and Buttery, 2009). Reduction of the tearing instability index by plasma flow shear was proposed as an explanation, and experimentally, the mode is observed to grow when the rotation is reduced (Politzer et al., 2008; Solomon et al., 2013). Differential flow also helps to stabilize the double tearing mode (Dewar and Persson, 1993), by decoupling the two rational surfaces.

Energetic-particle effects

Energetic particles (EPs), although a minority particle species in fusion plasmas in terms of particle number density, often play important roles in MHD instabilities. There are two main reasons for this. (i) EPs have much higher energy than the background particle species, so that the EP pressure, which is the product of the particle density and temperature, can sometimes contribute a significant fraction to the total plasma equilibrium pressure. As an example, fusion born alphas contribute more than 20% to the total pressure in an ITER advanced plasma scenario (Liu, 2010). This modification of equilibrium pressure due to EPs changes the MHD stability behavior of pressure driven modes. (ii) EPs can also directly interact with MHD perturbations and thus modifying the instability and even triggering new instabilities.

There are two key physics mechanisms involved in the direct interaction between EPs and MHD modes. One is the wave-particle Landau resonance. MHD modes can often be treated as (stable or unstable) waves. Wave-particle Landau resonances are used in many contexts in fusion devices. An important application is plasma heating by launching radial waves with frequency matching the cyclotron frequency of thermal ions or electrons.) When certain frequencies associated with the EP motion match the frequency of the MHD perturbation, free energy transfer between EPs and the MHD mode then ensues. The direction of the energy transfer, which determines whether the MHD mode is stabilized or destabilized, depends on many factors. The other physics mechanism is associated with trapped EPs, whose bounce motion forms a banana orbit that rotates along the toroidal angle of a tokamak. This toroidal motion of the banana orbit tends to conserve the vertical flux enclosed by the center line of the banana (Northrop, 1963). If the toroidal rotation frequency of the banana orbit is faster than the perturbation frequency, the mode can be stabilized.

Examples of EP stabilization of MHD modes include the IK (Porcelli, 1991, 1996; Graves, 2004), the RWM (Chapman et al., 2009; Liu, 2010), and the TM and NTM (Hegna and Bhattacharjee, 1989; Cai et al., 2011). TM/NTM stabilization by EPs may involve either direct interaction (Hegna and Bhattacharjee, 1989) or another, indirect way where EPs modify the external tearing index (Liu et al., 2012). Examples of EP triggering of MHD instabilities include the fishbone (Chen et al., 1984; Coppi and Porcelli, 1986), e-fishbone (Wong et al., 2000), Alfvén eigenmodes (Fu and Van Dam, 1989), and energetic particle modes (Chen, 1994).

Principal MHD instabilities

Overview

MHD instabilities are generally driven by a combination of electromagnetic and thermodynamic forces. The basic equilibrium relation Eq. (33) $\nabla P = \mathbf{j} \times \mathbf{B}$ describes the balance of these forces. Normally, instabilities are categorized as being either “current-driven” or “pressure-driven” depending on what is considered to be the major drive. For example, at zero pressure, the instabilities are naturally considered as “current-driven.” Onset criteria can be obtained in this limit. With pressure, instabilities that arise when the current-driven mode onset criteria are not satisfied are then usually considered as pressure-driven. This categorization works quite well in most cases since there are features in the mode structure that correspond to the distinction.

Within this categorization, a number of other labels are applied to various MHD instabilities. Early in the history of MHD, the first instabilities studied were called kink, flute, and sausage modes. The label “kink” or “external kink” is largely synonymous with “current-driven kink.” These are driven by a current density gradient or jump at the edge. Flute modes are an alternative term for pressure-driven interchange modes. The sausage instability corresponds to pressure-driven modes with poloidal mode number $m = 0$. Peeling modes are a subcategory of the external kink, corresponding to toroidal mode numbers $n > 1$.

Ballooning modes are pressure-driven. Normally the label is applied to the high- n version but pressure-driven modes at intermediate and low n all have the characteristic “ballooning structure” with a large coherent motion on the outboard side as field lines interchange locally there. Interchange modes are simply ballooning modes in the low shear limit where the interchange is global along the field line. Infernal modes, similarly refer to localized instabilities destabilized by a large pressure gradient in a locally low shear region. Bear in mind that these labels are really only valid in certain limits; most instabilities in real plasmas are a mixture of different features. The peeling-ballooning modes understood to be responsible for ELMs are a prime example of instabilities that defy characterization as either current driven or pressure driven (Snyder et al., 2002). Both the pressure and current-density gradients are important drivers. The IK, responsible for the sawtooth phenomenon in tokamaks, is another example. In a torus, the ideal IK is stable at zero pressure (Bussac et al., 1975), but has a very low β limit. The β limit also vanishes if the wall is removed (Turnbull and Troyon, 1989).

Axisymmetric modes are the ideal $n = 0$ instabilities. These are essentially current-driven in the sense that they are largely independent of the pressure and depend only on the gross features of the current profile. For a circular cross section, this mode is stable. In an elongated tokamak, the mode is a vertical shift ($m = \pm 1$).

For non-ideal modes, resistivity is an important driver of instabilities. Resistivity allows rational closed field lines to break and reconnect with a different topology. Two different modes can form corresponding to two different parities. An EK can result when two adjacent flux surfaces interchange position by breaking and reconnecting. This is the resistive version of the ideal kink mode. Alternatively, the closed rational surface can split with the two parts moving apart and opening up a magnetic island. The tearing apart of the surface provides the name “tearing mode.” This mode has no counterpart in ideal MHD. Fig. 3 shows how various MHD instabilities qualitatively look like, in terms of the radial distortion of the plasma caused by the instabilities.

Wesson identified the regions unstable to current driven modes in a model cylindrical plasma in the space of q_0 and q_s/q_0 (Wesson, 1978). Here, q_0 and q_s are the safety factor on axis and at the edge. These are the most important parameters determining current-driven instabilities. Fig. 4 is a corresponding “Wesson diagram” replotted in terms of q_0 and q_s for a generic strong Dee shape in

Fig. 3 Sketch of eigenmode structure, in terms of radial plasma displacement, for typical MHD instabilities: (A) internal kink (IK), (B) external kink (EK), (C) peeling mode (PM), (D) ballooning mode (BM), (E) infernal mode (IF), (F) tearing mode (TM), (G) interchange mode (IC).

Fig. 4 Regions in parameter space of different modes in the q_0 , q_s parameter space. Here, q_0 and q_s are the safety factor on axis and at the edge.

toroidal geometry with a monotonic current density profile and zero β . The boundary follows a generic stair-step pattern with steps at or near rational values of either q_0 or q_s . Changes in the current profile shape for fixed q_0 and q_s change the steepness of the staircase. However, there is no stable range in particular for $q_s < 2$ for any current profile. Pressure tends to smear the boundaries. Superimposed is the axisymmetric stability boundary and the general form of the stability limit against pressure driven kink modes for a fixed, finite β_p . The stable region is in the center. The slope of the axisymmetric boundary varies with $\mathcal{L}_i$. With increasing β_p , the pressure driven kink boundary dips to lower q_s . A generic ballooning stability boundary is also shown; again, the slope in this diagram varies with $\mathcal{L}_i$, also with β_p .

Axisymmetric modes

The axisymmetric instability is a vertical displacement of the plasma cross section in a vertical magnetic field. The plasma consists of a toroidal current in a vertical magnetic field. One can imagine a rigid elliptical cross section like an egg being squeezed by the vertical field. The shape of the egg diverts the lateral squeezing forces into a net vertical force and the egg slips rigidly in the field. Stability is determined then by the shape of the egg relative to the vertical field. For a plasma with an elliptical cross section, the plasma slips easily. Image currents in the wall generated by Lenz's Law, however, provide a stabilizing reaction force by opposing the fields generated by the vertical motion.

For a circular cross section plasma, the current loop is stable to a vertical shift. Essentially, for the plasma to slip up or down from its equilibrium position, it has to compress the external vertical field, requiring a source of energy. However, an elongated elliptical plasma can slip vertically with less distortion of the vertical field. For some elongation, the plasma becomes unstable to this motion and disrupts. For a large aspect ratio ellipse, the eigenmode is the pure axisymmetric vertical shift characterized by toroidal mode number $n = 0$ and an equal mix of poloidal mode numbers $m = \pm 1$ with constant amplitude as a function of radius;

$$\xi(r, \theta, \phi) = \xi_0(e^{i\theta} + e^{-i\theta}) \sim \xi_0 \cos\theta \quad (60)$$

In a torus there is some deviation from this due to the $1/R$ dependence of the fields. Additional $m = \pm 3$ components appear in a Dee shape and a stronger radial profile dependence of the $m = 1$ shift plus higher m components appear with higher order shaping.

In actual experiments, the instability is stabilized by a nearby surrounding conducting wall in which image currents are induced to oppose the magnetic field changes, preventing the perturbed flux from penetrating the wall (Lenz's Law). With finite resistivity, the image currents decay in a characteristic $1/R$ time and requires active feedback to fully stabilize it. (L and R are the wall inductance and resistivity, respectively.) The axisymmetric instability is well understood. Calculations of the ideal eigenfunctions have been shown to match the measured boundary displacements. In most cases, the observed open loop resistive wall growth rate can easily be fitted by simple plasma models assuming a rigid vertical displacement. This is generally sufficient for the feedback algorithms.

Internal kink, sawtooth, and fishbone

The IK mode, with toroidal mode number of $n = 1$ and poloidal mode number $m = 1$ was predicted by ideal MHD theory to be unstable early in fusion research. In a toroidal plasma, the $n = 1$ internal kink mode, as a linear eigenmode, has many poloidal harmonics. The $m = 1$ harmonic is dominant. However, some of the aspects associated with this mode, in particular the non-linear aspects and the interaction between this mode and energetic particles, are still active research areas. For recent research on the internal kink and sawteeth, see for example (Jardin et al., 2020).

From the MHD viewpoint, the primary driving mechanism for the IK instability is the free energy associated with the plasma current. More precisely, a critical condition for the mode instability is that the safety factor on the magnetic axis, q_0 , should be below 1. This condition is, however, not sufficient for an unstable IK. In a tokamak plasma, the IK becomes unstable only if the plasma pressure exceeds certain critical value. The mode growth rate γ , within the MHD framework, is in fact proportional to $(1 - q_0)(\beta_{pcr}^2 - \beta_p^2)$, where β_{pcr} is the critical value typically below 0.4. This is the well-known Bussac criterion (Bussac et al., 1975) for the IK instability. This criterion shows that the IK is also partly driven by the plasma pressure.

Because the mode growth rate is proportional to $(1 - q_0)$ (provided that the Bussac pressure limit is exceeded), the IK instability strength depends critically on the proximity of the on-axis safety factor to unity. In typical tokamak discharges, the on-axis safety factor is not far from 1, resulting in an IK that is not far from marginal stability. A weakly unstable IK is subject to a range of non-ideal effects beyond the ideal single-fluid MHD description. Important effects include the plasma diamagnetic stabilization, the plasma resistivity, and the drift kinetic effects associated with plasma particles. The diamagnetic stabilization of the IK is often referred to in the literature as the finite Larmor radius (FLR) effect, since it originates from the FLR of thermal ions. On top of these non-ideal effects, the plasma equilibrium toroidal flow also affects the mode stability. In what follows, we briefly discuss each of these effects.

A weakly unstable IK is often subject to strong diamagnetic stabilization in a tokamak plasma (Ara et al., 1978). This is because the typical mode growth rate in this case is comparable to the thermal ion diamagnetic frequency. The dispersion relation for the mode (complex) frequency ω satisfies $[\omega(\omega_i^* - \omega)]^{0.5} = -\delta W$, where ω_i^* is the thermal ion diamagnetic frequency and δW is the normalized perturbed potential energy. δW here is normalized by the plasma inertia. As usual, $\delta W < 0$ indicates free potential energy that drives instability. In the absence of the diamagnetic stabilization, and for a purely growing IK mode, the mode growth rate scales linearly with the perturbed potential energy.

Plasma toroidal flow can be either stabilizing or destabilizing to the IK. The fundamental physics mechanism for flow stabilization of the IK is the so-called gyroscopic stabilization (Wahlberg and Bondeson, 2000), where the perturbation, which has a rigid structure, is stabilized by fast rotation. The required rotation speed for full stabilization of the mode has to be very large (a large fraction of sound speed). The flow shear, on the other hand, can destabilize the IK essentially due to the Kelvin-Helmholtz type of mechanism. Associated with toroidal flow are various inertial forces (centrifugal and Coriolis forces), which can be either stabilizing or destabilizing depending on the equilibrium profiles (Wu et al., 2019).

Non-linear evolution of the IK often manifests itself as the sawtooth phenomenon, which is observed in experiments. There are different theoretical models for sawteeth. The first and probably the most well-known model is the Kadomtsev model (Kadomtsev, 1975), where full magnetic reconnection was assumed within the $q = 1$ surface during the non-linear evolution.

Lastly, drift kinetic effects, in particular those associated with toroidal precession of trapped EPs, can have significant influence on the IK stability and the sawteeth behavior. Drift kinetic effects from thermal particles can also stabilize the IK (Hu et al., 2006), although the effect is often not dramatic. These effects are well summarized by the Porcelli model (Porcelli et al., 1996), where three different criteria were proposed to judge the IK instability and the subsequent onset of sawteeth. These Porcelli criteria have been successfully applied to interpret many experimental results in tokamak plasmas.

Drift kinetic effects of EPs not only stabilize the IK, but can also drive a new type of instability called the fishbone mode (FB). The word "fishbone" originates from the characteristic magnetic signals observed in experiments, which is actually a result of a non-linear interaction between the instability and EPs (Chen et al., 1984; Porcelli, 1991; Porcelli et al., 1996). The fundamental physics here is the wave-particle Landau resonance, where an otherwise stable IK absorbs free energy from EPs, and thus becomes unstable. Since the mode is driven unstable by EPs, the mode frequency matches that of the characteristic frequency of the drift motion of EPs. The most common case is again the toroidal precession of trapped EPs. Another drive is associated with diamagnetic rotation of EPs. Plasma resistivity often stabilizes the FB (Biglari and Chen, 1986; Wu et al., 2018)—an effect opposite to that for the IK. For the FB, the resistive layer dissipates the free energy.

EK/Resistive-wall modes (RWMs)

There are two drive mechanisms for the external kink instability, the plasma pressure and the plasma current. The purely current driven EK mode has been studied since early on in fusion research (Shafranov, 1970; Wesson, 1978). A key milestone in realizing the importance of pressure effects was the discovery of the Troyon β limit (Troyon et al., 1984), showing that the maximal achievable normalized plasma pressure, before the discharge disrupts, scales in proportion to the normalized plasma current, as shown in Eq. (41).

Plasma pressure is the most typical drive in present and future tokamak devices. This mechanism resembles the ballooning drive. In fact, the eigenmode associated with the pressure driven EK is typically localized at the outboard low-field side of the torus, similar to the ballooning instability. This type of EK is therefore also often called kink-ballooning instability. An important distinction with the ballooning instability, however, is the toroidal mode number associated with the perturbation. The EK is the long wavelength global MHD instability along the toroidal (and poloidal) angle, with a typical toroidal mode number of $n = 1 - 3$, while the ballooning instability has typical toroidal mode numbers greater than 10.

For the EK driven unstable in a low-pressure plasma by the plasma current, when the nq_s value (in a limiter plasma) is just below an integer m , an instability results with toroidal mode number n , and predominantly poloidal mode number m , which causes a large plasma displacement near the plasma edge. For $n > 1$ and $m > 2$, this instability is often called a kink-peeling mode. When the plasma current is sufficiently high in a limiter plasma that q_s is below 2 (Wesson, 1978), this always triggers a strongly unstable $n = 1$ EK which leads to plasma disruption if not suppressed.

In a plasma with a divertor configuration, the edge safety factor is large (mathematically infinite at the separatrix). The associated large magnetic shear near the plasma edge can stabilize the resulting mode (Webster and Gimblett, 2009). Despite the magnetic shear stabilization, a disruptive instability is still often observed in divertor experiments when the safety factor at the 95% flux surface, q_{95} , approaches 2.0. This puzzle was recently resolved by invoking the effect from a steep edge plasma resistivity profile (Turnbull et al., 2016).

Independent of the drive mechanism, it has been found that the presence of an ideal conducting wall, located sufficiently close to the plasma, can stabilize the ideal EK instability up to a certain limit. In reality, the wall almost always has finite conductivity. This allows partial escape of the perturbed radial magnetic field, on a time scale comparable to the eddy current decay time in the resistive wall. As a result, the EK again becomes unstable in the q_s or q_{95} parameter windows as described above, but now on a much longer time scale. This slowly growing instability is called the RWM (Chu and Okabayashi, 2010). Note that the resistivity here refers to that of the resistivity wall, not the plasma. The resistive-plasma resistive-wall mode is another interesting topic that has been under extensive studies in recent years (Betti, 1998; Finn, 2006).

The eigenmode structure of the RWM still remains global, similar to that the EK (Subtle differences in the mode structure for the resonant harmonics near the mode rational surfaces appear for the RWM in a toroidal plasma, which often do not play a significant role.). The mode growth rate is, however, significantly reduced as mentioned. This has several significant implications. (i) The presence of this residual instability means that the RWM can potentially still cause a serious disruption of the plasma. (ii) The much lower growth rate, or in general much lower (complex) mode frequency, implies other physics beyond ideal MHD may play important roles. (iii) The much longer time scale of the RWM growth, in milliseconds or longer, also makes it practical to design an active control system to actively stabilize the mode.

There exist several passive stabilization mechanisms for the RWM utilizing additional physics beyond ideal MHD. The first important effect is continuum resonance damping of the mode in a toroidally rotating plasma. Unlike many other MHD modes, the RWM, even in the linear regime, does not rotate with the plasma. A tokamak plasma typically rotates at a frequency of several percent of the Alfvén frequency along the toroidal direction. There are many reasons for finite toroidal rotation, e.g., due to toroidal momentum source associated with tangential neutral-beam injection, the presence of intrinsic toroidal torque. The RWM, on the other hand, has a frequency that is of the same order of the much smaller inverse wall time; the RWM appears to be essentially “locked” to the resistive wall. The mode thus rotates in the plasma frame, opening the possibility of Landau resonances between the mode and various continuous waves (which rotate together with the plasma), such as the shear Alfvén waves and sound waves (more precisely slow magneto-acoustic waves). Since these continuum waves are stable, they can tap free energy from the RWM through resonances, thus stabilizing the mode. Such a mechanism was discovered numerically in a seminal work by Bondeson and Ward (1994) and later analytically confirmed Betti and Freiberg (1995).

Numerical modeling finds that the above stabilization mechanism often requires a plasma toroidal rotation of several percent of the Alfvén frequency (Bondeson and Ward, 1994; Chu et al., 1995; La Haye et al., 2004), in order to fully suppress the RWM in a tokamak plasma. Later experiments (Reimerdes et al., 2007), where the plasma toroidal flow was intentionally kept slow by balanced neutral-beam injection, the RWM instability did not occur even when the plasma pressure exceeded the no-wall Troyon limit, contradicting theory predictions. The puzzle is resolved by evoking additional physics, namely drift kinetic theory (Hu and Betti, 2004), where Landau resonances between the mode and the drift motion of plasma thermal particle species become important. Indeed, because the toroidal precessional drift frequency of trapped thermal particles (both ions and electrons) is typically very low (well below the thermal particle diamagnetic drift frequency), a strong resonance occurs if the RWM also has a small frequency in the plasma frame, which is the case when the plasma toroidal rotation is slow. Since then, precessional drift-kinetic stabilization of the RWM has been confirmed by extensive numerical modeling work (Liu et al., 2008; Chapman et al., 2009; Berkery et al., 2010). The MHD-kinetic hybrid description of the RWM instability still remains an active research area.

Resistive interchange/TM/NTM/locked modes

The resistive interchange (RI) mode and the TM are the two most important spatially localized resistive instabilities. There are many interchange instabilities in fusion plasmas. For instance, the so-called sausage instability in a Z-pinch can also be viewed as an interchange instability based on the fundamental drive mechanism. Those with finite toroidal mode number and poloidal mode number $m > 1$ are most important. Compared to the TM, the interchange mode has opposite parity. More specifically, if we define the mode parity by the associated radial plasma displacement, the interchange mode has even parity (i.e., symmetric about the mode rational surface) and the TM has odd parity (i.e., anti-symmetric about the mode rational surface).

Both instabilities are driven by finite plasma resistivity (assuming that the ideal counterparts are stable), by allowing a change in the magnetic topology near the rational surface. According to the Mercier criterion (Mercier, 1960), the ideal interchange is unstable if a quantity $D_I = D_R + \frac{1}{2}$ is positive. D_R is proportional to the equilibrium pressure gradient at the mode rational surface. However, the resistive interchange is unstable if D_R is positive. An equilibrium with zero or negative D_R , on the other hand, can be unstable to the TM. Since the latter typically holds for a tokamak plasma, the RI mode is usually not as critical as the TM. (Even if a resistive interchange is unstable in a tokamak plasma, it can be easily stabilized by plasma rotation.) The following will therefore focus on the TM and its neoclassical counterpart, the NTM.

The linear TM instability is driven unstable by the plasma current profile. Because the mode displacement is strongly localized near a rational surface, the instability is often studied via a matching procedure, where the ideal MHD equations at marginal stability are solved and the solution is matched to that of the resistive MHD equations within a narrow layer around the rational surface. Typically, the perturbed radial field (or magnetic flux) is used to perform the matching procedure. The logarithmic derivative of the outer ideal solution experiences a jump across the mode rational surface. This jump, denoted as Δ' , characterizes the free energy associated with the equilibrium current density gradient that drives the TM unstable. The outer solutions are matched to the non-ideal solution obtained in a narrow inner layer around the rational surface to produce a continuous solution. In a pressureless plasma, the matching condition yields a simple relation between the mode growth rate γ and Δ' , $A\gamma^{5/4}\eta^{-3/4} = \Delta'$, with η being the plasma resistivity and $A > 0$ a geometric factor. This dispersion relation implies that the TM is unstable whenever the tearing index Δ' is positive, and that the mode growth rate scales as $\gamma \sim \eta^{3/5}$.

In an equilibrium with finite pressure (more precisely with finite negative D_R), an important effect, namely the so-called favorable average curvature effect, becomes important and modifies the TM dispersion relation to a form $A\gamma^{5/4}\eta^{-3/4}(1 - ED_R\gamma^{-3/2}\eta^{1/2}) = \Delta'$, where $E > 0$ is now another geometric factor (Glasser et al., 1975). This new physical effect, coming from the resistive layer solution, qualitatively changes the TM stability criterion. Then, Δ' has to be larger than a critical positive number, in order to ensure the TM instability. In other words, this average curvature effect plays a stabilizing role (thus “favorable”) to the TM instability. This is one of the key physics elements associated with the TM in a toroidal plasma. Later studies found additional interesting layer physics that modify the TM dispersion relation, e.g., a large island correction that restores the $\gamma \sim \eta^{3/5}$ scaling at high resistivity (Militello et al., 2004), and a cancelation effect on the favorable curvature stabilization due to anisotropic thermal transport (Lutjens et al., 2001; Connor et al., 2015).

Because of the strong radial localization of the instability, non-linear effects are important for the TM. A critical consequence of a developing TM instability is the change of the magnetic topology near the mode rational surface, where a chain of magnetic islands with helical structure forms. Essentially all the non-linear effects are related to the local change of the plasma current in the presence of magnetic islands. The first non-linear effect was identified by Furth et al. (1963), and leads to an algebraically (instead of exponentially) growing magnetic island. Later studies identified an important role played by the neoclassical bootstrap current (Qu and Callen, 1985; Fitzpatrick, 1995; Wilson et al., 1996), that modifies the TM stability and results in the neoclassical tearing mode (NTM). The bootstrap current is stabilizing to the TM. If, however, a portion of the bootstrap current is missing in the presence of 3D magnetic islands, the stabilizing role is reduced and the NTM can be triggered. Note that there can be different ways to change the bootstrap current, e.g., due to particle flattening of the plasma pressure profile inside the magnetic islands (Fitzpatrick, 1995) or due to induced polarization current (Wilson et al., 1996). All these effects involve the finite island size and are thus intrinsically non-linear, requiring a threshold in the island size. (There have been discussions on triggerless/seedless NTM which presumably originate from a linearly unstable TM due to large and positive Δ').

The time evolution of the NTM islands is well described by the quasi-linear Modified Rutherford Equation (MRE) (Sauter et al., 1997; Turnbull et al., 2002), which includes these effects, but excludes nonlinear coupling to other toroidal mode components with different n . The other non-linear effect is the interplay between a growing island and the plasma toroidal rotation. This is important for a full understanding of locked modes (LMs), which correspond to the locking of an NTM to the wall. This is, in fact one of the major causes of plasma disruptions in experiments (besides VDE and EK discussed before). Mode locking, as well as NTM control, will be discussed in the later section on MHD stability control.

Toroidal Alfvén eigenmodes

The Hermitian nature of ideal MHD implies that the squared frequency, ω^2 , which is the eigenvalue, is always real. Stable modes correspond to those with non-negative ω^2 . In the cylindrical approximation, it can be shown that the ideal MHD spectrum consists of a possible set of discrete or isolated unstable modes and a continuum of irregular modes on the stable side arising where the coefficient of the second order term in the eigenvalue equation vanishes. These continuum modes are highly localized at the point where the coefficient vanishes and actually consist of two overlapping continua corresponding to sound waves and Alfvén waves,

respectively. In the ideal limit, they have infinite energy but are regularized by non-ideal effects. On the unstable side, the eigenmodes correspond to the array of physical ideal MHD instabilities discussed above. There can be a finite (or zero) number of unstable modes or a countably infinite number. In the latter case, generally corresponding to violation of the local Mercier criterion, the eigenvalues have an accumulation point at marginal stability. The stable spectrum is shown in Fig. 5. In ideal MHD the stable continuum modes are purely oscillatory and have no damping or drive, lying on the imaginary axis in ω space. In reality, they tend to be strongly damped by various non-ideal effects, most notably ion Landau damping.

This situation persists in toroidal geometry but with an important modification. In the cylinder, there is a separate continuum for each poloidal mode number m . In the torus, the equations for different m are coupled and near the crossing points, degenerate perturbation theory applies and the curve crossings are replaced by the reconnected curves shown, leaving gaps in the frequency. This is shown in Fig. 5A. Within the gaps, global regular eigenmodes appear in the Alfvén continuum at isolated frequencies. These consist of coupled m and $m + 1$ components with a typical example shown in Fig. 5B. Again, in ideal MHD these are purely oscillatory modes with no damping. However, the non-ideal damping of the irregular continuum modes is inversely proportional to the radial wavelength and is greatly weakened for this global mode. In particular, when the gaps overlap across a wide radius, there is no radius at which this global mode interacts with or couples to a localized continuum mode and the damping becomes small. Instead, these modes are relatively easily driven unstable. These are known as the toroidal Alfvén modes (TAEs).

The frequencies of typical TAE and other similar higher frequency global modes are generally sufficiently high that the damping rates are much smaller; $\omega_{TAE} \gg \gamma_{damp} \sim \gamma_{drive}$. In that case, the ideal estimate of the real frequency is generally sufficiently accurate and the drive and damping can be computed using the computed ideal mode. The non-ideal effects simply add an additional

Fig. 5 (A) The continuous spectrum formed from frequencies ω^2 , at which the coefficient vanishes against radius for different m and showing the TAE, BAE, and EAE gaps. (B) TAE mode structure consisting of coupled m and $m + 1$ components.

imaginary part to $\omega_{TAE} \rightarrow \omega_{TAE} + i(\gamma_{drive} - \gamma_{damp})$, corresponding to a growth or damping rate. For most situations this is a valid assumption. In addition to the weakened ion Landau damping, several other non-ideal mechanisms dampen the TAE and other stable global modes. The most important of these is the so-called “continuum damping,” which results when an open gap does not extend all the way across the radius. In that case, the TAE at one broad location couples directly to a continuum mode (irregular in ideal MHD), inheriting its large inherent ion Landau damping. Several kinetic effects provide additional damping sources but more important, result in a second global mode in the gap at higher frequency. This is known as the Kinetic Toroidal Alfvén Eigenmode (KTAE) and has no MHD counterpart. The instability drive of most interest is from fast non-thermal ions via an inverse ion Landau process. Such ions are typically present in current experiments as a result of external ion heating of the plasma by either neutral-beam injection or RF waves. In future experiments, the concern is that energetic alpha particles from the fusion reaction would provide the drive.

In the case of radio frequency (RF) waves, the waves themselves can be designed to resonate at Alfvén-like frequencies and used to probe the plasma. When the external RF wave resonates with a stable MHD plasma wave as the frequency is varied, the width of the resonance peak provides a measure of the inverse of the damping rate of the mode. This technique, called MHD Spectroscopy, has been used to study the stable Alfvén continuum spectrum as well as low frequency marginally stabilized MHD kink modes.

In addition to toroidicity, other geometric effects can couple the poloidal harmonics and break open new gaps in the continuum. The most important of these are ellipticity and triangularity, with their corresponding global Ellipticity Alfvén Eigenmode (EAE) and Triangularity Alfvén Eigenmode. With finite β , the Alfvén continuum lifts off the marginal point $\omega^2 = 0$ leaving another gap below with width proportional to β_p . The gap is filled with sound wave continua. With respect to the discrete frequencies of these modes and their gaps, the effect of finite β appears to raise them by an amount roughly proportional to β_p . However, relative to the gap, the global mode moves slightly down in frequency with increasing β_p (Turnbull et al., 1993).

This lower gap is known as the Beta-induced Alfvén Eigenmode (BAE) gap (Turnbull et al., 1993). Early experiments searching for the TAE mode also found global Alfvén-like modes within the BAE gap. Numerical searching subsequently found global largely single harmonic modes sitting in this gap. Theory is somewhat complicated for these modes since the usual assumptions of small coupling to the sound waves are not really valid, although the numerical calculations included it. The key physics in this mode is compressibility. The gap and mode are associated with the energy required by a global Alfvén wave to compress as it moves in the curved torus. This is in contrast to a sound wave that propagates as an actual compressional wave. Ignoring compressibility to eliminate the sound waves also eliminates the BAE physics.

Several other Alfvén eigenmodes were discovered in experiments that revealed so-called “chirping modes,” in which the observed frequency “chirped up” until the mode disappeared or would be converted to a TAE mode. Ideal stable modes associated with these were subsequently found in continuum gaps that resulted from these particular discharges having an off-axis reversal in the q profile. Hence, they were called Reverse-shear Alfvén Eigenmodes (RSAEs) (Kramer and Fu, 2006). The gap was determined at any time by q_{min} which varied in time and explained the chirping behavior. Intermittent behavior sometimes results from a periodic expulsion of the fast ions driving the mode unstable, thereby suddenly stabilizing it, and a reforming of the previous beam distribution and plasma conditions.

Edge localized modes (ELMs)

Edge localized modes (ELMs) are instabilities driven by the large edge pedestal pressure gradient and its associated bootstrap current in tokamak H-mode plasmas. ELMs are generally divided into different types such as Type I-IV and “grassy” (Leonard, 2014). Not all these types of ELMs are driven by macroscopic MHD modes. For instance, the type-III ELM is believed to be driven by micro-tearing mode (Snipes et al., 1998). The focus in the following discussion is on Type-I ELMs which have macroscopic MHD origin. More importantly, Type-I ELMs have been experimentally demonstrated to lead to unacceptable material erosion in future reactor-scale tokamaks by inducing thermal and particle fluxes onto the plasma facing components.

Type-I ELMs can be explained by a model for edge localized modes as predominantly ideal instabilities with low to intermediate toroidal mode number. This idea was around for some years (Turnbull et al., 1986; Strait, 1994), and was proposed in later years on the basis of ideal MHD stability calculations for DIII-D discharges using a model for the pressure driven bootstrap current included in the equilibrium reconstruction and DIII-D ELM experiments (Osborne et al., 1999; Ferron et al., 2000; Lao et al., 2001; Snyder et al., 2002). This current produces a large current density peak near the edge of the plasma sufficient to destabilize low to intermediate n instabilities driven partly by that current density gradient (peeling mode component) and partly by the edge pressure gradient (ballooning mode component). The peeling-ballooning model has since been incorporated into a model known as the EPED model that combines the MHD peeling-ballooning stability limit with other non-MHD limits to predict the actual ELM onset (Snyder et al., 2009, 2011). This was made possible by the development of the ELITE (Edge Localized Instabilities in Tokamak Experiments) edge stability code to efficiently compute intermediate to high n modes (Wilson et al., 2002; Snyder et al., 2002).

The basic MHD instabilities behind Type I ELMs are known as peeling-ballooning modes. The external kink mode, when becoming unstable at relatively high edge safety factor (more precisely at high nq_{95}), tends to localize near the plasma edge with a large kink component driven by the strong bootstrap current gradient, as well as a peeling component at the separatrix, and a low to intermediate n toroidal mode number. This is called kink-peeling mode or simply peeling mode. The other component of the Type I ELM is the ballooning mode, which is typically a short wavelength perturbation along both toroidal and poloidal angle, and is geometrically localized near the plasma outboard edge at the low field side. The ballooning mode is described as local instability here in a relative sense. Sometimes, the mode with finite (but large n) is referred to as non-local, in comparison to the infinite- n ballooning mode

which is localized on magnetic flux surfaces. The ballooning instability is driven by the plasma pressure, more precisely the large pressure gradient near the plasma edge. Since large pressure gradients occur in H-mode plasmas with large edge pedestals, the latter is the primary free energy source driving ballooning instability in a tokamak plasma. Note that with further increase of the plasma pressure, the ballooning mode can enter into a second stability regime (Greene and Chance, 1981). This is primarily because higher pressure increases the Shafranov shift and compresses the equilibrium magnetic field lines in the low field side of a tokamak plasma, which is stabilizing for MHD instabilities. Because the ballooning mode is a high- n perturbation, the full MHD equations can be significantly reduced in order to efficiently but approximately describe this instability, by dropping higher order terms in $1/n$. A critical analytic development is discovery of the so-called ballooning representation (Connor et al., 1978), which allows a more natural (in physics sense) representation of the eigenmode structure and substantially facilitates theoretical (and often numerical as well) analysis of this mode. The extension of the ballooning formalism to higher order in $1/n$ enabled development of the ELITE code (Wilson et al., 2002; Snyder et al., 2002).

The ballooning mode is also subject to many physics effects beyond the single-fluid ideal MHD description (Connor et al., 1988). The most important one among these effects is the diamagnetic stabilization of the mode (Rogers and Drake, 1999; Hastie et al., 2000; Snyder et al., 2011). Based on understanding of both the ideal and non-ideal physics, a theoretical model—the EPED model (Snyder et al., 2009, 2011)—has been developed to predict the plasma pedestal conditions for onset of Type I ELMs. The key idea of the model is the realization that the pedestal structure—both the height and width—can be constrained by two modes in a tokamak H-mode plasma. One is the peeling-ballooning constraint and the other constraint is due to a more localized, transport type of instability such as the kinetic ballooning mode. These two modes constrain the pedestal height and width following two different scaling curves, and their intersection indicates what is realizable in experiments. The EPED model has been successfully applied to a range of tokamak experiments (Snyder et al., 2011). In addition, the model predicted the existence of, and the access route to, a new high performance plasma regime called super-H mode that was subsequently realized in experiments (Solomon et al., 2014, 2016; Snyder et al., 2015, 2019; Hughes et al., 2018; Knolker et al., 2020).

The EPED model reproduces the triggering mechanism of type I ELMs well (Snyder et al., 2011). However, the ELMs observed experimentally represent a highly non-linear stage of the instability. For instance, the filamentary structure that is observed in experiments inside the plasma separatrix is no longer a linear ballooning instability. This is an ongoing area of theoretical research.

Finally, there are ELM-stable regimes in tokamak plasmas. These ELM-stable regimes are favorable for tokamak operations due to their benign feature and thus minimizing bursts of heat and particle fluxes reaching the plasma facing components. The L-mode is ELM-stable but is not particularly attractive in terms of energy confinement. In the context of high confinement regimes, the QH-mode (Burrell et al., 2001, 2016) and I-mode (Whyte et al., 2010) regimes are two promising candidates without ELMs. The former often has a saturated MHD instability (the so-called Edge Harmonic Oscillation EHO) that helps to provide necessary transport in the pedestal region to avoid ELMs. Recent studies also identified a QH-regime with wide pedestal, where no EHOs are needed to provide transport (Burrell et al., 2016). The latter does not require an edge pedestal in the plasma density, only pedestal in plasma temperature, which helps avoid ELM triggering but meanwhile maintains good particle and energy confinement. Furthermore, application of 3D magnetic perturbations near the plasma edge also helps to suppress ELMs and produces ELM-stable regimes (Evans et al., 2004). Of particular recent interest are plasmas with negative triangularity shape (Medvedev et al., 2015; Ren et al., 2016; Austin et al., 2019; Kikuchi et al., 2019), which can also provide an ELM-stable high confinement regime. Negative triangularity equilibria generally do not have favorable average magnetic curvature, resulting in strong ballooning instabilities that suppress the formation of an edge pedestal and hence in many cases the discharges remain in L-mode, with no ELMs, even at high power.

Stable plasma response to external 3D fields

Since plasmas consist of unbound free charges, the charges individually respond and the plasma collectively responds to applied external fields. The predominant immediate response is electromagnetic and the MHD formalism captures this well. In essence, the plasma responds by setting up Alfvén waves that propagate through the system and re-establish local force balance everywhere forming a new 3D equilibrium state:

$$\nabla \cdot (\mathbb{P} + \delta\mathbb{P}) = \mu_0 (\nabla \times (\mathbb{B} + \delta\mathbb{B})) \times (\mathbb{B} + \delta\mathbb{B}) \quad (61)$$

This state generally has different transport properties from the original unperturbed state. For example, topological changes, particularly the presence of open field lines, can modify transport dramatically. Hence, following the MHD response, there is a longer term, transport response.

The response of the plasma is important for understanding several related phenomena. Early in tokamak fusion research, the phenomenon of locked modes plagued progress. Depending on the density, a rotating tearing mode would arise and as it grew, slow the plasma, amplifying the growth further, until the plasma locked to an error field fixed with respect to the vessel wall and usually subsequently disrupted. In studying resistive wall modes, near the stability limit it was observed that non-axisymmetric error fields were strongly amplified (Wang et al., 2015). Furthermore, in experiments designed to suppress ELMs, suppression was found but not by the mechanism expected. The mechanism involves the plasma response but is still not fully explained. One robust indicator of ELM controllability appears to be the edge-peeling response of the plasma to the applied 3D fields (Liu et al., 2016), valid for both mitigation (Liu, 2011; Ryan et al., 2015; Li et al., 2016) and suppression (Paz-Soldan et al., 2015; Yang et al., 2016).

When an external field is applied, the most obvious response on a particle level is that, just as in any conductor, currents flow in the plasma to oppose the changes by excluding the field from penetrating the plasma. Thus, the first response is for skin currents to

flow in the edge. These currents are singular on closed rational field lines that resonate with a harmonic of the perturbed normal field: when $q = m/n$, for a field harmonic $\delta B_{n, m}(r)e^{i(m\theta - nq\phi)}$, with a delta function radial dependence of the current density. However, finite resistivity in the plasma implies these currents decay and, unless regenerated, the field slowly penetrates. Effective regeneration of the currents can occur from plasma rotation. In pioneering work, [Fitzpatrick and Hender \(1991\)](#), [Fitzpatrick \(1993, 1995\)](#) demonstrated that non-ideal effects result in a complex nonlinear interaction between the rotation and the perturbing 3D field where the field slowly removes and dissipates rotational energy as it penetrates, slowing the rotation further, and enhancing the penetration. The result is a bifurcation in the rotation, with two dynamically stable states, one at high rotation with little penetration and the other at low rotation, essentially locked in the laboratory frame, with a fully penetrated field. In between is an inaccessible, dynamically unstable state. The net result of this is that by applying an external 3D field, the plasma rotation subsequently slows and locks to the wall. The plasma response at first expels the external field but subsequently incorporates it in a locked stationary state. The response is a nonlinear dynamic response with suppression occurring first, followed by a slow penetration depending on the resistivity and the plasma rotation.

The second major component of the plasma response is generally an amplification. This was first noted in numerical calculations of the linear MHD response where the expected suppression of specific field harmonics of the normal field component was observed at the respective rational surfaces but became finite again inside. This is attributed to coupling of the poloidal harmonics: non-resonant harmonics penetrate beyond the rational surface and drive the suppressed component back up, amplifying it.

These two parts of the MHD response are, in fact, inseparable. The total linearized response can be expressed as an expansion in the eigenfunctions of the linear eigenmodes of the ideal MHD operator $\partial^2 \xi / \partial t^2 - \mathcal{L}\xi = 0$, so that $\xi = \sum_{k=1}^{\infty} a_k \xi_k$, where $\mathcal{L}\xi_k = \lambda_k \xi_k = -\omega_k^2 \xi_k$, with λ_k being the eigenvalue and ω_k the frequency. The eigenmodes ξ_k inherently include the suppression of the resonant field harmonics at the rational surfaces and amplification in their structure. For ideal MHD, the eigenmodes of $\mathcal{L}$ form a complete orthonormal basis, so any possible ideal response can be expressed completely in the expansion. The non-ideal response, however, can have contributions not in the basis corresponding to tearing solutions.

By applying an external RF field with different frequencies, the ideal MHD eigenmodes can be probed by measuring the response. For this case, by substituting the expansion for the response ξ in terms of the ξ_k into the dynamic equation of motion for a driven perturbation, $\partial^2 \xi / \partial t^2 - \mathcal{L}\xi = A_0 e^{i\omega_0 t}$, one finds

$$\xi(r, t) = \sum_{k=1}^{\infty} [a_k / (\omega_k^2 - \omega_0^2)] \xi_k(r) \quad (62a)$$

$$a_k \equiv \int \xi(r, t) A_0 e^{i\omega_0 t} d^3 r \quad (62b)$$

The response has a resonant denominator proportional to $\omega_k^2 - \omega_0^2$ that vanishes whenever the driving frequency ω_0 coincides with a characteristic frequency of the ideal system. By measuring an aspect of the response as the frequency is varied, a series of peaks appears at these eigenfrequencies. It can also be shown that the width in frequency of the peaks is inversely proportional to the (non-ideal) damping rate. This procedure, dubbed “MHD spectroscopy” ([Reimerdes et al., 2004](#)) has been used in experiments to probe both the stable Alfvén spectrum, identifying TAE and other Alfvén eigenmodes, as well as marginally stabilized kink modes. The technique seems likely to become more prominent in the future.

The transport response follows from the changes in topology, edge conditions, and profiles due to the initial MHD response. With no topological changes, the local transport coefficients can be different as a result of changes in local profiles. When islands form, the transport is completely changed, not only from the island itself, but also because island formation necessitates formation of an associated local chaotic region. In the chaotic regions, parallel transport becomes important and competitive with perpendicular transport. Finally, when the field lines open and leave the plasma region, the global transport becomes a complex mixture of parallel and perpendicular transport, with various chaotic structures playing important roles.

There are several characteristic transport effects that are typically observed. Foremost of these is the observed rotation drag discussed above. The rotation screens the applied fields from penetrating the plasma, essentially by regenerating the screening currents formed at rational surfaces. However, the fields themselves provide a back effect by slowing the rotation. As the rotation slows, the fields are able to penetrate more easily and finally the rotation collapses to a new bifurcated locked state with fully penetrated field and decayed singular currents. The second most important observed effect is the “pump-out” effect. The root cause of this is the formation of open field lines connecting the edge plasma layers to the exterior vacuum and material structures. Along with this pump-out effect is a generally observed reduction in core impurities.

Numerical tools

Many numerical tools have been developed for modeling MHD instabilities in fusion devices, and these tools can be classified in many different ways. We will pursue two ways of classifications here for a list of well-known MHD codes, one is based on whether the code solves linear or non-linear MHD equations, and the other is based on which physics are included into the codes. We emphasize that what we provide below is not a full list of MHD codes that have been developed and used by the MHD community.

Many codes have been developed during the last 40 years, that are capable of solving linear MHD equations in full toroidal geometry, and are well validated against experiments. The linear stability problem can always be solved as an eigenvalue problem.

These codes are therefore mostly written as eigenvalue solvers, including PEST-II (Grimm et al., 1983), ERATO (Gruber et al., 1981), GATO (Bernard et al., 1981), NOVA (Cheng and Chance, 1987), MARS (Bondeson et al., 1992), DCON (Glasser, 1997), KINX (Degtyarev et al., 1997), MISHKA (Mikhailovskii et al., 1997), MARG2D (Tokuda and Watanabe, 1999), MARS-F (Liu and Bondeson, 2000), ELITE (Wilson et al., 2002; Snyder et al., 2007), AEGIS (Zheng and Kotschenreuther, 2006), and MINERVA (Aiba et al., 2009). Some of the codes were also developed into new versions with significant inclusion of drift kinetic effects, such as NOVA-K (Cheng, 1992), MARS-K (Liu et al., 2008), AEGIS-K (Zheng et al., 2010). The non-linear MHD codes include NIMROD (Glasser et al., 1999; Sovinec et al., 2004), M3D (Park et al., 1999), M3D-C1 (Ferraro and Jardin, 2009), JOEKE (Huysmans and Czarny, 2007; Pamela et al., 2020), BOUT (Xu and Cohen, 1998), BOUT++ (Dudson et al., 2009). The MARS-Q code actually solves the quasi-linear MHD equations by including the nonlinear interaction of the mode and the rotation (Liu et al., 2013).

In terms of physics, several early codes solve ideal, single-fluid MHD equations, such as ERATO, GATO, NOVA, and DCON. These are all linear codes. Because the ideal MHD energy principle has the important Hermitian property, most of these ideal MHD codes are based on the ideal MHD energy principle. Exceptions are the AEGIS code, which is based on the shooting method, and the NOVA code. There are also linear MHD codes that solve resistive MHD equations. These are typically based on the normal mode eigenvalue approach, such as the MARS code. Codes that solve the extended MHD equations (including two-fluid) are usually non-linear. These include M3D-C1, NIMROD, JOEKE, and BOUT++. Codes that solve the hybrid MHD-kinetic equations include NOVA-K, M3D-K, MARS-K, AEGIS-K, and NIMROD (a version with kinetic treatment of energetic particles).

Principles of control for MHD instabilities

Fusion gain can be expressed in terms of the fusion power P_F and input power P_I as $Q = P_F/P_I \sim \tau_E \beta^* B^2 \sim \tau_E p_f \beta_T B^2$, where τ_E is the energy confinement time and the pressure profile peaking factor p_f is defined as $p_f^2 \equiv \langle p^2 \rangle / \langle p \rangle^2$, and $\beta^* \equiv p_f \beta_T$. Thus, Q can be increased by increasing β_T and keeping all other factors constant. But, from the Troyon limit equation, Eqs. (41) and (42), β_T is limited by stability. Hence, one needs to optimize $\beta_T \lesssim \beta_T^{crit} = k_\beta \mathcal{L}_i (I_p / a B_T)$ against all the important instabilities. A useful view can be reached by then rewriting the maximum fusion gain as (Lazarus et al., 1997)

$$Q = [R_0^2 B_T^2] \times \left[p_f k_\beta \mathcal{L}_i (S^2 / \kappa) (H^2 / q_s^2) \right] \quad (63)$$

Here, H is a confinement enhancement factor relative to H-mode ($1 \leq H \leq 2$), and q_s is the boundary q , or for a divertor plasma, q_{95} . $R_0 = (R_{max} + R_{min})/2$ is the average of the maximum and minimum of the major radius of the plasma boundary. The plasma shaping enters here directly in terms of the shaping factor $S = q_s (I_p / a B_T)$ and the elongation κ . The current profile dependence appears directly through the internal inductance parameter $\mathcal{L}_i$.

The first factor enclosed in square brackets is a technological factor and a reactor has a direct cost roughly proportional to this factor. The rest contains quantities directly related to plasma physics. All but the confinement factor H are stability related and can be increased by optimization with respect to pressure peaking, cross section shape, and safety factor. The improvement in stability against pressure driven modes from cross section shaping is embodied largely in the factor S^2 / κ . Q can be increased by simply increasing this factor, thereby increasing $I_p / (a B_T)$ and hence β_T . This reflects the fact that $n > 0$ stability is improved by increasing S . However, S^2 / κ is limited by axisymmetric stability.

Optimization from profiles is embodied in the factors $p_f k_\beta \mathcal{L}_i$ and $1/q_s^2$. The pressure profile peaking factor p_f is limited by $n > 0$ stability. There is also a synergistic dependence of the β_T limit on cross section and profiles. For high S , the limiting stable k_β has an inverse dependence on p_f and the product is generally optimized by low p_f , whereas at low S , the dependence of k_β on p_f is weaker. The current profile factor $\mathcal{L}_i$ is limited by $n = 0$ stability. Stability to current driven modes provides a limit on how low q_s can be.

Advanced Tokamak operation

By optimizing against the second factor in the expression for Q above, essentially maximizing the β_T limit, β_T^{crit} , a smaller, more compact tokamak with reduced major radius R_0 and B_T can match the performance of larger, high field machines. Ultimately, this requires the stabilization of instabilities. The Advanced Tokamak (AT) concept follows this route. Control of the profiles pushes the discharge into a state with higher stability limits and maintains it there. Therefore, most AT approaches require some level of active feedback.

Control requires three key elements, namely sensors to detect deviations in the system state from the desired values, actuators to reposition the system toward the desired state, and control algorithms to convert the sensor signals to actuator commands. In the fusion plasma context, the sensors are diagnostic techniques for measuring the required aspects of the plasma state. The actuators are the means of affecting the plasma, for example, external heating, current drive and fueling systems, as well as external fields used to reconfigure the equilibrium or induce a particular plasma response. The control algorithms are essentially mathematical prescriptions, usually based on simplified (reduced) models for determining the actuator commands from diagnostic measurements.

In an AT, control of the equilibrium profiles is an essential element. This includes startup of the discharge, a steady state period, and a final shutdown. In the startup and shutdown phases, the major issue in practice is maintaining MHD stability of the plasma. In the steady state phase, the major issue is to optimize the profiles for high performance, while still avoiding MHD unstable states. Evolutionary paths to this state need to be stable at each point. Active feedback control of incipient instabilities is also essential. Active

feedback stabilization of the axisymmetric (vertical) instability is routine. Typically, the plasma position (for example the current centroid) or a number of points on the plasma boundary, the isoflux control points, are found and, if displaced from its target position or target boundary points, additional axisymmetric fields are used to reposition it (Ferron et al., 1998; Huang et al., 2020) by programming the currents in the external poloidal-field coils. Active stabilization of the non-axisymmetric RWM is similar in principal but requires a more complex set of sensors and applied field distribution (Liu et al., 2000, 2004). In practice, as discussed, sufficient plasma rotation passively stabilizes the RWM but the marginal RWM amplifies error fields which then slow the rotation, leading to destabilization of the RWM. In a reactor, active feedback stabilization of the RWM is likely required. Control of intermittent instabilities such as sawteeth and ELMs typically take the approach of either mitigating their effects or avoiding them through control of the equilibrium profiles. The other major control issue is the need to avoid and mitigate disruptions, which will be discussed in the next section.

MHD theory provides the basis for defining the algorithms used to relate diagnostic sensor measurements to actuator controls. Typically, the algorithms use simplified models but these are often derived from full MHD predictions and are generally tested against them.

Control of MHD instabilities

Sawteeth result in a transfer of the core energy inside the $q = 1$ surface to the outside. They are normally relatively benign but if the $q = 1$ radius is large and the core pressure high, an abnormally large amount of energy can be lost. This can happen in cases where the sawtooth period is very long, the so-called giant sawteeth, allowing a large amount of energy to build up in the core, followed by a large and fast crash that disturbs a large part of the cross section. These need to be avoided. Note that, like ELMs, sawteeth can be beneficial by periodically expelling impurities from the fusing core. Thus, it is advantageous in many cases to control the sawtooth rate, keeping it short. Control options that have been considered involve controlling the radius of the $q = 1$ surface. Control using RF waves, particularly Electron and Ion Cyclotron Current Drive (ECCD and ICCD) has been considered to modify the current and pressure profiles around the $q = 1$ surface and tried. Another option is to run in sawtooth free regimes. This simply means controlling the profiles so that q remains well above one, avoiding completely the 1/1 internal mode (ideal or resistive). This is the solution envisaged in the Advanced Tokamak concept.

TMs born rotating with frequency near local plasma rotation and saturate at some amplitude. But these islands slow the plasma rotation (Fitzpatrick and Hender, 1991) and the plasma and mode lock. At that point, the mode generally grows rapidly as wall stabilization is lost, and disrupts the plasma. The mode typically locks in a fixed phase relationship with a pre-existing error field. Threshold scalings have been obtained from experiments and can be used to avoid low and high-density locked modes. The thresholds also depend on the pre-existing error field. These modes can be partially controlled by maintaining the plasma rotation against the natural slowing that results from the incipient instability. This entails feedback on the momentum input to the plasma.

Control of NTMs has been demonstrated (La Haye et al., 2002) using ECCD to replace the reduced bootstrap current that results from the reduced pressure gradient inside the islands. A control scheme called “search and suppress” has been developed whereby the island is detected and ECCD is directed using mirrors to locally be deposited in the island center. An alternative strategy under development is to modify the local current density using ECCD, essentially changing the local Δ' . This can also be modified by applying additional helical fields. For tearing modes that are destabilized by proximity to the ideal MHD β limit (Brennan et al., 2002), the modes are linearly unstable and Δ' provides the major drive and this is the most promising strategy.

Control of the RWM follows the same strategy as the routine stabilization of the axisymmetric mode. For that case, the technique has been in use routinely since the 1970s and refined since the 1990s (Lazarus et al., 1990; Ferron et al., 1998; Liu et al., 2000; Strait, 2015). The ideal instability is slowed by a resistive wall from a growth time of the order of a plasma Alfvén time $\tau_A \sim 10^{-6}$ sec to the wall L/R time—the time scale for stabilizing image currents to decay. The fields are then sensed and growing fields suppressed by applying an opposing field. In the non-axisymmetric case, the major complication is the need for more sensors and actuators.

ELM control falls into four major categories usually referred to as ELM-stable, ELM-free, ELM mitigation, or ELM suppression. The first refers to plasma configurations such as QH mode or I-mode in which there are no ELMs. Control in this case is mostly concerned with maintaining the plasma operating conditions so that it stays in QH or I-mode. The second refers to plasma configurations for which the peeling-ballooning instability is suppressed for a long period. Typically, however, these are not stationary and an ELM finally appears that is larger than usual, similar to the situation with giant sawteeth. Control in this case appears to require control of the equilibrium profiles to avoid the final instability. ELM mitigation means changing conditions to replace the large Type-I ELMs by smaller, more frequent ELMs, either small Type I or Type II or Type III. Suppression, in contrast, refers to removal by full stabilization of the Type-I ELMs. ELM-free regimes however, suffer from the problem that, without ELMs, impurities and density build up in the core. ELMs do have a beneficial effect of removing core impurities, or helium ash in the case of a reactor. Mitigation solves this problem. Control of the ELM frequency in this case can be done using ELM pacing, with triggering by pellets (Lang et al., 2004a; Baylor et al., 2013), vertical kicks (Lang et al., 2004b), applied non-axisymmetric fields (Canik et al., 2010), or applied modulated non-axisymmetric fields (Solomon et al., 2012). On the other hand, ELM suppression regimes do not result in an impurity buildup. These are obtained for certain plasma parameter regimes by applying non-axisymmetric fields (Evans et al., 2004).

Disruption physics, prediction, prevention, and mitigation

A critical issue in tokamak experiments is the occurrence of plasma disruptions, where the discharges abruptly terminate with many undesirable consequences (ITER Physics Basis Editors, 1999b; Hender et al., 2007). The causes of disruption are complicated and are not always fully understood. These can be grossly divided into MHD and non-MHD causes. We will mainly discuss the MHD causes here. Many non-MHD causes are often directly or indirectly related to MHD events, e.g., the presence of MHD precursors, the presence of large magnetic islands in the radiative cooling model that explains the plasma density limit induced disruption (Gates and Delgado-Aparicio, 2012).

As described before, there are several macroscopic MHD instabilities that can cause plasma disruption. One is the external kink mode including the resistive wall mode. The current-driven external kink becomes very dangerous when the edge safety factor (q_s for limiter plasmas and q_{95} for divertor plasmas) approaches the value of 2. The pressure-driven external kink can cause disruption when the Troyon limit is exceeded. The other important MHD cause is mode locking, which typically occurs when the 2/1 tearing mode becomes unstable and large magnetic islands are created which (at least locally) break the plasma toroidal rotation.

A typical plasma disruption has two characteristic time scales, related to the thermal quench (TQ) and current quench (CQ). The first process, where the plasma thermal energy is rapidly lost, typically lasts a couple of milliseconds. This is a very fast process, likely involving many non-linear MHD events. The TQ is followed by the much longer CQ phase, where the plasma current resistively decays and eventually vanishes (together with the magnetic energy stored in the plasma). The time scale of the CQ depends on tokamak devices and in particular on the poloidal cross-section area (ITER Physics Basis Editors, 1999b; Hender et al., 2007).

There are two important consequences associated with plasma disruption. One is the electromagnetic force acting on the conducting structures surrounding the plasma, typically the vacuum vessel and the supporting structures. This force can be large during disruption and can potentially damage the PFCs and in-vessel structures. The other critical consequence is the generation of high-energy electrons with speed close to the light speed. These so-called runaway electrons can potentially melt the PFCs, and thus must be controlled in future reactor scale devices such as ITER.

Disruption prediction and avoidance

As mentioned before, since disruptions may have different origins, predicting them is generally challenging. If a disruption is caused by MHD event, there are often magnetic precursors that can be employed, but the reliability is always an issue. Since the late 1990s, methods based on artificial intelligence (AI) have been used for the purpose of disruption prediction in tokamak experiments (Wroblewski et al., 1997), with significant progress being made during recent years (Kates-Harbeck et al., 2019; Zhu et al., 2021). This approach requires a large operation database to train the AI algorithm (e.g., the neural network), before it can be used for predicting future experiments. Proper selection of the equilibrium input data, besides the AI architecture and the training algorithm, is critical for the success of the AI based approaches. For predicting specific classes of disruption, model-based approaches are also highly valuable. Examples are the DECAF model (Berkey et al., 2017) based on various MHD events, and the recent initiative of the predict-first approach (Lyons et al., 2018).

Disruption avoidance is a passive way of operating the plasma discharge. Based on a-priori knowledge, certain types of disruptions, in particular those involving MHD instabilities, are predictable. This knowledge can be used to constrain the discharge parameters to avoid entering into the dangerous range. For instance, the plasma pressure can be limited to be below the Troyon limit (often following the $\mathcal{L}_i$ scaling in Eq. (42)) during the operation. The plasma current and toroidal field can be designed to avoid the edge safety factor reaching below 2. By various methods, the toroidal rotation speed can be maintained at a certain level to avoid locked modes. With both disruption prediction and avoidance, it is important to realize that accurate and fast equilibrium reconstruction is a critical element.

Disruption mitigation

As discussed, development of effective strategies to mitigate and control tokamak disruption is critical to reduce and avoid potential damage to the PFCs and in-vessel structures. All mitigation methods rely on rapid injection of high charge number Z impurities into the plasma to radiate away most of the plasma thermal energy. MHD provides a useful model to develop and test techniques to mitigate and control MHD instabilities.

A leading candidate for a disruption mitigation system (DMS) is the shattered pellet injection (SPI) approach in which a stream of cryogenic cooled pellets is injected into a bended tube and shattered into small fragments before entering into the plasma to allow higher assimilation and more rapid delivery of injected impurities than a gas injection system (Shiraki et al., 2016; Baylor et al., 2019). Another promising technique is the dispersive shell-pellet injection (DSPI) method in which a low- Z hollow shell filled with a dispersive payload is injected into the plasma to allow a deep penetration of impurities into the plasma core and a more effective inside-out thermal quench (Izzo and Parks, 2017; Hollmann et al., 2019).

An accurate disruption mitigation simulation requires integration of a global 3D MHD code with a local pellet ablation code (Kim et al., 2019; Bosviel et al., 2021). Progress has been made to model disruption mitigation by impurity injection and interpretation of SPI and DSPI experiments with the NIMROD (Kim et al., 2019; Izzo et al., 2020), M3D-C1 (Lyons et al., 2019; Ferraro et al., 2019) and JOEREK (Hu et al., 2018; Pamela et al., 2020) 3D MHD codes using simplified reduced pellet ablation models. NIMROD predictions of DIII-D SPI and DSPI results are consistent with DIII-D experimental observations. An animation of a NIMROD simulation of DIII-D dual-injector SPI simulation is illustrated in Fig. 6 (Kim et al., 2020). However, significant

Fig. 6 NIMROD animation of a DIII-D dual-injector SPI simulation showing magnetic field lines and contours of plasma radiation and injected impurity concentration. Courtesy of Kim CC, et al. (2020) *Simulations and Validation of Disruption Mitigation and Projections to ITER's Disruption Mitigation System*. Bulletin of the American Physical Society C007.00015. <https://meetings.aps.org/Meeting/DPP20/Session/C007.15>.

challenges remain to develop a robust and effective disruption mitigation technique and their simulations and validations that can address all the disruption issues, particularly regarding the generation and mitigation of runaway electrons (Boozer, 2017; Lehnert et al., 2020; Sweeney et al., 2020).

Summary

MHD provides a useful model to describe the crucial plasma macroscopic equilibrium and stability behaviors in toroidal tokamak devices. The MHD equations provide a set of comprehensive physics constraints to understand and interpret tokamak macroscopic instabilities. Principal MHD instabilities include the internal kink modes, sawtooth, fishbone, external kink, resistive wall mode (RWM), resistive interchange, tearing and neoclassical tearing modes (NTMs), locked modes, toroidal Alfvén eigenmodes (TAEs), and edge localized modes (ELMs). Predictions from MHD theory are consistent with many observed features of these instabilities. Fast-growing MHD instabilities can lead to an abrupt plasma disruption and termination that can potentially damage the device PFCs and in-vessel structures. An important MHD application is to develop robust techniques to mitigate and control instabilities. These include control of NTMs and RWMs, mitigation and suppression of ELMs, and disruption avoidance and mitigation.

Glossary

Advanced Tokamak scenario Has been developed for tokamak continuous operation in a fusion power plant and is characterized by reversed magnetic shear, or q-profile radial dependence, in the central plasma region.

Boozer coordinates A set of magnetic coordinates often used in fusion simulations to simulate EP drift motion ([Boozer, 2004](#)). Their use is beneficial for the Hamiltonian formulation of charged ion orbit drift motion.

Cyclotron instabilities Instabilities which have a frequency comparable with the characteristic frequency of the cyclotron gyro rotation in the magnetic field of the plasma.

Electron Coulomb logarithm It is a factor by which the small-angle electron-plasma collisions are more effective than large-angle collisions. For many plasmas of interest it takes on values between 5 and 10. (For convenient formulas, see pages 34 and 35 of the [NRL Plasma formulary](#).)

Geodesic Acoustic Modes Low frequency oscillations strongly interacting with thermal ions (see [Jenko, 2020](#)).

Krook collision operator A simplified way to include the relaxation of a plasma ion distribution function in the Boltzmann kinetic equation.

Reversed shear plasma Plasma characterized by $\frac{dq(r)}{dr} < 0$ in the central region of the plasma.

Nomenclature

β_N Normalized plasma pressure, $= \% \beta / (I/aB_\phi)$

λ_e Electron Coulomb logarithm

BAE Beta-induced Alfvén eigenmode

CAE Compressional Alfvén eigenmode

EAE Ellipticity-induced Alfvén eigenmode

GAE Global Alfvén eigenmode
 GAM Geodesic acoustic modes
 ICRH Ion cyclotron radiofrequency heating (see [Dumont, 2021](#))
 LHD Large helical device (see [Yamada, 2021](#))
 NPA Neutral particle analyzer
 RSAE Reversed shear Alfvén eigenmode
 TAE Toroidicity-induced Alfvén eigenmode
 WDM Whole device modeling (see [Jenko, 2021](#))

Introduction

We consider energetic particles as a superthermal ion population which is required to sustain the burning conditions in the presence of inevitable energy losses from the plasma. As such EP includes (1) fusion products, primarily alphas particles, from deuterium-tritium fusion reaction, (2) energetic beam ions such as planned 1 MeV deuterium ions in ITER reactor, and (3) H-minority ions accelerated by ion cyclotron radiofrequency heating (ICRH).

This article is written with the aim of discussing what might be considered traditional aspects of EP physics, including Alfvénic instabilities, by developing the underlying physics understanding of these topics. We start this article with the description of a single particle confinement in section “**Single particle confinement**.” Then we present the basic elements of wave-particle interaction including the Alfvénic eigenmodes and low frequency, Alfvén acoustic modes in section “**Wave particle interactions**,” which covers the linear theory of Alfvénic eigenmodes. It gives the EP physics a strong base for applications and projections to burning plasmas. Nonlinear elements of EP physics, covered in section “**Nonlinear evolution of EP-driven modes and energetic particle transport**,” are currently investigated by many groups in the world and considerable progress has been made. Their development is becoming critical for making quantitative predictions, as discussed in section “**Implications for burning plasmas**.”

For further reading we recommend the following review papers on several aspects of EP physics which are covered in great details in topical review articles ([Heidbrink, 2008](#); [Cheng, 1992](#); [Kolesnichenko et al., 2011](#); [Toi et al., 2011](#); [Breizman and Sharapov, 2011](#); [Lauber, 2013](#)) as well as in comprehensive reviews ([Heidbrink and Sadler, 1994](#); [Gorelenkov et al., 2014](#); [Chen and Zonca, 2016](#)). These are natural extensions of earlier reviews ([Mikhailovskii, 1975](#); [Kolesnichenko, 1980](#)).

We consider EP physics to be a key element of the research toward making fusion a feasible component of sustainable energy sources. For the purpose of this encyclopedia, the article follows main elements of a recent review ([Gorelenkov et al., 2014](#)) which is recommended for further reading and references.

Single particle confinement

Drift motion. EP moment conservation in axisymmetric and in 3D plasmas

An energetic ion in the presence of a strong magnetic field, B , moves along the field line with parallel speed, $v_{\parallel}$, while rotating in the perpendicular direction around the center of the gyro-orbit with Larmor radius, $\rho_f = v_{\perp}/\omega_c$, where $v_{\perp}$ is the perpendicular speed. At the same time, the ion slowly drifts in the direction perpendicular to vector, B , with the drift velocity, $v_d = \frac{B}{B\omega_c} \times [(2\varepsilon_{\parallel}\kappa + (\varepsilon_{\perp}/B)\nabla B)]$, where $\omega_c = eB/mc$ is the cyclotron frequency, $\varepsilon_{\parallel}$ and $\varepsilon_{\perp}$ are the parallel and perpendicular component of particle energy variable given below at Eq. (1), e and m are the ion charge and the mass, and c is the speed of the light.

On a longer timescale EPs slow down by interacting with thermal ions and electrons with the characteristic slowing down time determined primarily by electrons $\tau_{se}[\text{sec}] \approx 0.01(10/\lambda_e)(m_i/m_p z_i^2) \frac{(T_e[\text{eV}])^{3/2}}{n_e} [10^{20} \text{ cm}^{-3}]$, where fast ion is denoted as a specie i , λ_e is the Coulomb logarithm of electrons, T_e and n_e are the temperature and the density of thermal electrons. The EP distribution function is formed as described below in section “**Slowing down distribution function of fast ions in quiescent plasmas**.”

The EP drift motion is described by three constants of motion: energy, $\mathcal{E}$, adiabatic moment, μ , and canonical angular momentum, P_{φ} :

$$\mathcal{E} = v^2/2; \mu = \varepsilon_{\perp}/B; P_{\varphi} = v_{\varphi} c R m / e - \psi_p, \quad (1)$$

where ψ_p is the poloidal flux function of the magnetic surface, subscript φ refers to the toroidal angle component.

The conservation of μ and P_{φ} is well-established in tokamak geometry.

In spherical tokamaks (or STs) μ and P_{φ} are conserved, although, as given by Eq. (1), they oscillate in time ([Belova et al., 2003](#)). For test particle simulations, it is often sufficient to know that there are expressions for μ and P_{φ} that are conserved, but the explicit expressions often are not required. More accurate expressions are required for the problems where the phase information of fast ion drift motion is needed, such as for cyclotron instabilities.

Fig. 1 Energetic proton or alpha particle guiding center trajectories in JET tokamak at energy 9.54 MeV and magnetic field 3.5 T. Different types of orbits shown in the figure are characteristic for the drift motion of the charged ions including thermal ions. They have different drift frequencies which are responsible for different wave-particle interactions.

The toroidal angular momentum as describe by Eq. (1) is, strictly speaking, not an adiabatic invariant in 3D configurations due to the lack of toroidal symmetry in the magnetic field (see also Galvão and Canal, 2020; Yamada, 2021). Nevertheless, an adiabatic invariant exists for a wide class of three dimensional geometries such as stellarator/helical devices where the rotational transform per toroidal field period is small, $(1/2\pi)/N \ll 1$, and the strength of the field does not change much due to toroidicity as compared to the variation along the field line due to the helical ripple, i.e., $\varepsilon_\phi(1/2\pi)/(\varepsilon_h N) \ll 1$ (Cary et al., 1988). Here we denote the rotational transform (or field line pitch) as $1/2\pi$, which defines the number of poloidal transits per single toroidal transit of a field line on a toroidal flux surface, N is the toroidal field period number, ε_ϕ and ε_h are the quantities which represent the relative magnetic field variation due to toroidicity and relative magnetic field ripple due to the helical coils, respectively (Cary et al., 1988).

In such 3D devices, two classes of particles exist. Particles of one class are trapped in local magnetic field ripple wells and others are untrapped. The former, trapped, particles have a bounce invariant or a modified second adiabatic invariant J^* and the latter (passing) also have an invariant. For passing particles with small pitch angle the invariant becomes equivalent to the toroidal angular momentum P_ϕ . The J^* conservation was successfully applied to the study of particle orbits in the ATF device that satisfied both requirements: $(1/2\pi)/N \ll 1$ and $\varepsilon_\phi(1/2\pi)/(\varepsilon_h N) \ll 1$ (Rome, 1995). In the LHD configuration with large $N = 10$, the toroidal angular momentum is conserved for passing EPs. The requirements defined above are not satisfied for quasi-axisymmetric helical devices with small $N = 2$ or 3. We note that the above requirements are satisfied even near the plasma edge and therefore the P_ϕ is approximately conserved from the plasma core to the edge.

Fig. 1 presents several guiding center orbits in the JET tokamak (White, 2006). The considered case corresponds to the plasma equilibrium with a major radius of 299 cm and EP gyroradius 9 cm, i.e., a fast proton or alpha particle having an energy of 9.54 MeV. Several types of orbits are shown: a,b,l are passing particle orbits, e,c are trapped particle orbits whereas c is the orbit of a lost particle. A more detailed discussion of particle orbits can be found in Sarazin (2021). Characteristic EP parameters in various tokamaks and in ITER are given in Table 1.

Ripple and other axisymmetry breaking effects on EP confinement

The confining magnetic field in conventional tokamaks is created by the finite number of the toroidal field coils (Galvão and Canal, 2020) in such a way that the equilibrium magnetic field is changing along the field line, i.e., in other words, it is modulated by poloidal and toroidal angles, ϑ and φ respectively, $B = B_0[1 - (r/R) \cos \vartheta + \delta \cos N\varphi]$, where $\delta = (B_{\max} - B_{\min})/(B_{\max} + B_{\min})$ is typically on the order of 1% on the low field side of the tokamak. It becomes negligibly small at the magnetic axis.

At that level the ripple losses are small, resulting in a few percent of α -particle losses in ITER (Fasoli et al., 2007). One of the consequences of the equilibrium rippled magnetic field is the dependence of its absolute value along the toroidal direction. The rate at which the trapped particle drifts out of the plasma is fast, $v_d = R\omega_c(\rho_f/R)^2$, which results from the direct drift velocity in the tokamak equilibrium field.

There is a critical value for the ripple magnitude above which an EP ion becomes unconfined. For the case of low β , cylindrical equilibrium and at a bounce point of the EP trajectory, $\vartheta_b = \pi/2$:

Table 1 Energetic ion parameters for various tokamak heating systems.

Parameter Machine	$P_t(0)$ [MW/m ³]	$n_t(0)/n_e(0)$ [%]	$\beta_t(0)$ [%]	$\langle\beta_t\rangle$ [%]	Max $ R \nabla\beta_t $	$V_t/V_A(0)$

$$\delta > \delta_{cr} = \left(\frac{\varepsilon}{N\pi q} \right)^{3/2} \frac{1}{2\rho_f q'} \quad (2)$$

The magnitude of a magnetic field ripple, given by Eq. (2), is known as the Goldston-White-Boozer (GWB) critical ripple magnitude, which is often used for a rapid analysis of the ripple strength. Experimentally the ripple diffusion boundaries (see below) and/or the fraction of the losses of charged particles are measured in order to understand the EP classical confinement in the present day devices and to make projection for burning plasmas (Heidbrink and Sadler, 1994; Zweben et al., 2000). An important point in the above measurements is that the particle transport is expected to be *diffusive* in the ripple domain, i.e., the trapped ion motion is described by the diffusion term in the drift kinetic equation (Gorelenkov et al., 1997). The diffusion of the trapped particles was inferred by the PCX diagnostic in TFTR (Medley et al., 1996).

Slowing down distribution function of fast ions in quiescent plasmas

The energetic ion distribution function (DF) is the key integral characterization of all the effects on those particles from various physics phenomena. It accumulates the effects that the EPs encounter into a dependence on energy, pitch angle and canonical momentum, provided these effects influence the EPs within one slowing-down time. Examples of such effects include classical non-collective as well as collective effects due to waves and instabilities.

There are direct measurements of the EP distribution function available, e.g., by using an experimental technique in which energetic ions are neutralized by gaining electrons from a lithium pellet injected into the plasma and immediately leave the plasma as energetic neutrals, being detected at the plasma edge by a Neutral Particle Analyzer (NPA) (Medley et al., 1996).

Examples of such measurements are shown in Fig. 2 for fusion products, alpha-particles, in TFTR DT experiments (Gorelenkov et al., 1997). This illustrates the evolution of the alpha-particle energy distribution function during the alpha slowing down phase from near the birth time of the alpha-particles. One can see that the DF slows from the alpha-particle source near 3.52 MeV, computed at 0.12 s after the start of additional heating, down to the distribution function taken at 1.2 s.

To compute the alpha-particle DF, consider the relaxation of the classically confined EP distribution function given the known source of DT fusion alphas. The drift kinetic equation for the fast ion distribution function (DF) f , leaving only the source and the drag terms, is:

$$\frac{1}{\tau_{se} v^2} \frac{\partial}{\partial v} (v^3 + v_*^3) f - S_f(v) = 0, \quad (3)$$

where v_*^3 is the characteristic ion speed when the slowing down on electrons is equal to the slowing down on ions.

One can solve this equation for a delta-function source in velocity source, $S_f(v) \sim \delta(v - v_{j0})$:

$$F_{se} \approx \frac{3}{2^5 \pi^2} \frac{B^2 \beta_f}{E_f (v^3 + v_*^3)}, \quad (4)$$

which has the slowing down distribution function dependence, where the speed at birth, v_{j0} , corresponds to a birth energy, E_f .

Eq. (4) is a Green function of the inhomogeneous first order differential equation (3), the solution of which can be written through the integral for any source function such as the Gaussian in velocity, $S_f(v) = S_{j0} \int \exp[-(v' - v_{j0})^2 / \Delta_v^2] \delta(v' - v) dv'$. Substituting this and the Green function (4) into the equation (3) we obtain an expression which is the same as (4) if $v < v_{j0}$ and an integral of the EP source function near the birth velocity v_{j0} , which is a complementary error function, $\text{erfc}(x) = 1 - \text{erf}(x)$:

Fig. 2 Evolution of DT fusion alpha energy DF spectra computed using the FPPT code (curves, (Gorelenkov et al., 1997)) and its comparison with measured by the lithium Pellet Charge eXchange (PCX) diagnostic (Medley et al., 1996) alpha spectra. The measurements were performed at two time, 0.12 and 1.2 s after Li pellet injection as indicated.

$$F = F_{se} \operatorname{erfc} \left[(v - v_{f0}) / \sqrt{4\nu} \right] / 2. \quad (5)$$

This has a smooth behavior near the EP birth velocity, which can be applied to either α -particles or neutral beam injected ions near the beam injection velocity.

Wave particle interactions

Fusion-born alpha-particles, as well as the auxiliary heating ions such as the beam ions, in next-step burning plasma experiments will have longitudinal velocities comparable to the Alfvén speed $v_A = B / \sqrt{4\pi m_i n_{pl}}$, where n_{pl} is the plasma density, but well decoupled from both electron and ion thermal velocities of the bulk plasma, $v_{Ti} \ll v_A \sim v_\alpha \ll v_{Te}$. Under these conditions, shear Alfvén perturbations (see section “Collective effects” for more details) could resonate effectively with the fast ion population and release free energy associated with, e.g., the alpha-particle pressure gradient. At the same time, the resonant interaction of shear Alfvén waves with the thermal plasma species is exponentially small, and other damping mechanisms become dominant, such as radiative and continuum damping. In the case of Toroidal Alfvén Eigenmodes (TAEs having their eigenfrequencies in the gaps of the Alfvén continuum (see illustrations in Fig. 4 of such gaps)), the continuum damping of TAEs becomes weak, and the drive from alpha-particles could overcome the other damping mechanisms, leading to TAE excitation. In addition to shear Alfvén waves, the EP population could also excite compressional Alfvén waves, geodesic acoustic modes, and ion sound acoustic waves. In present day experiments, observed oscillations (such as TAEs) can be often characterized by their gradual frequency evolution, which occurs on an equilibrium time scale (Gorelenkov et al., 2014). Different nonlinear scenarios are considered in the next section “Nonlinear evolution of EP-driven modes and energetic particle transport.”

The interaction of EPs with waves and eigenmodes, particularly those having an “Alfvénic” character, is considered to be potentially a significant limitation of the tokamak-reactor performance (Fasoli et al., 2007). We should note that in most practically relevant cases wave-particle interactions (WPI) occur between the resonant beam ions or fusion products and the eigenmodes, or standing solutions, of 3 (generally coupled) fundamental oscillations. Those oscillations include sound (or acoustic), shear and compressional (or magnetosonic) Alfvén waves.

Interaction between waves and particles include an interesting, but, speculative, idea, worth mentioning here, to utilize energetic alpha particles through the so-called alpha-channeling effect (Fisch and Rax, 1992; Herrmann and Fisch, 1997). Alpha channeling diverts the energy from energetic alpha particles to plasma waves in order to avoid that energy simply heating electrons. Rather, that energy can be used to directly heat the fuel ions or can be used to amplify plasma waves that drive electric currents. The alpha channeling could result in a more economical deuterium–tritium tokamak reactor. Simulations and experiments on TFTR support certain separate building blocks that taken together might produce the desired effect (Fisch, 2000).

Collective effects

MHD and kinetic descriptions

Linear and nonlinear analyses of MHD modes have proven to be important for design and operation of fusion devices (Wesson, 1997; see also Lao et al., 2021). The ideal MHD model is based on the set of equations obtained from velocity moments of the

kinetic equations for thermal ions and electrons. These have the form of MHD equations, i.e., the plasma looks like a fluid that can carry the current and can be augmented by infinitely large conductivity, i.e., with vanishing electric field along the magnetic field line, $E_{\parallel} = 0$.

The quadratic form is important to understand the power balance in the wave-particle interactions and in MHD stability in general (Lao et al., 2021). It can be obtained by integrating the equations of motion of plasma particles

$$\delta W + \delta K = 0; \delta K = -\frac{\omega^2}{2} \int \rho (\vec{\xi})^2 dx^3; \delta W = -\frac{1}{2} \int \vec{\xi} \cdot \vec{F}(\vec{\xi}) dx^3. \quad (6)$$

Here δW and δK are the plasma potential and kinetic energies. ρ is the plasma mass density, $\vec{\xi}$ is the plasma displacement vector, $\vec{F}$ is the force acting on the plasma element.

This quadratic form is a useful constraint imposed on plasma oscillations to characterize the stability properties of the system within certain limits by providing the tools to find the real frequency and its imaginary part:

$$\omega_r^2 = 2\delta W / \int \rho \vec{\xi}^2 dx^3, \quad \omega_i / \omega_r = -\Im \delta W / 2\delta K. \quad (7)$$

The real part of δW is found using the force balance equation and can be written in the form

$$\delta W = -\frac{1}{2} \int \left[\frac{1}{c} \vec{\xi}_{\perp}^* \cdot \delta(\vec{J} \times \vec{B}) - \vec{\xi}_{\perp}^* \cdot \nabla \delta p_c \right] d^3x, \quad (8)$$

where the plasma displacement includes both incompressible Alfvén and compressible acoustic parts. Various forms of the potential energy of oscillations exist in the literature (Chen et al., 1984; Bussac et al., 1975; Wesson, 1997).

The kinetic EP contribution, δW_f , relies on the derivation of the EP perturbed distribution function, which is obtained by solving the drift kinetic equation and represents the most general way to find the growth rate in the linear perturbative theory of tokamaks (Porcelli et al., 1994; Gorelenkov et al., 1999). The expressions for δW_f can be written using the constants of motion (COM) variables. Then the EP contribution follows:

$$\delta W_f = -\frac{4m_f^2 \pi^2 c \omega}{e_f} \int dP_{\phi} d\mu d\mathcal{E} \tau_b \sum_{mm'l'} \mathcal{E}^2 F'_{\mathcal{E}} \frac{G_{ml}^* G_{ml} (1 - \omega_*/\omega)}{\omega - n\bar{\omega}_D - l\omega_b}, \quad (9)$$

where the drive is coming from the radial gradient of the EP distribution, $\omega_* = n(F_{p_{\phi}}/F'_{\mathcal{E}}) \sim n d\beta_f/dr$, $G_{ml} \sim v_d^* E$ represents the wave-particle interaction matrixes, and the toroidal mode number is explicitly introduced in the resonant denominator to underline its role in the resonance condition. The denominator in this expression determines the resonances by specifying the poloidal harmonic number and the bounce frequency. The coefficients, G_{ml} , are the harmonics of the EP—wave interactions, the scalar product $\vec{v} \cdot \vec{E}_{\perp}$, gyro averaged over time. Eqs. (9), (7) are standard for the perturbative theory to compute the growth and damping rates of the Alfvénic modes due to the resonances with ions or electrons (Mikhailovskii, 1975).

A knowledge of the resonances in phase space is important to understand whether the excitation of certain AEs may or may not lead to effective particle transport.

Alfvén eigenmodes, TAEs and other global Alfvénic modes

The Alfvén eigenmodes driven by energetic particles are often observed in tokamak plasmas. They belong to primarily one of three fundamental MHD branches, which is the shear Alfvén branch. In MHD theory, in general one can cast the plasma oscillations into a single equation for the plasma displacement vector, $\vec{\xi}$:

$$\frac{\partial^2 \vec{\xi}}{\partial t^2} = v_A^2 \nabla (\nabla \cdot \vec{\xi}) + v_A^2 \nabla_{\perp} (\nabla \cdot \vec{\xi}_{\perp}) + v_A^2 \frac{\partial^2 \vec{\xi}_{\perp}}{\partial z^2}. \quad (10)$$

The RHS of this equation contains three types of waves. One of them is the shear Alfvén oscillations, whose dispersion follows from this equation if the parallel component of the displacement to the magnetic field line and $\nabla \cdot \vec{\xi}_{\perp}$ are vanishing. Then the Alfvénic branch displacement has the form:

$$\frac{\partial^2 \vec{\xi}_{\perp}}{\partial t^2} = v_A^2 \frac{\partial^2 \vec{\xi}_{\perp}}{\partial z^2} \text{ or } \omega^2 = \omega_A^2 = v_A^2 k_{\parallel}^2. \quad (11)$$

Any solution of this equation written in a cylinder can be represented as a superposition of waves propagating along the z axis with the Alfvén velocity v_A . The parallel component of the wavevector for the axisymmetric plasmas in tokamaks is $k_{\parallel} = (m - nq)/qR$. Here m and n are the poloidal and toroidal mode numbers respectively.

In a toroidal plasma, poloidal harmonics are coupled due to the poloidal variation of the equilibrium magnetic field. The coupling is thus between the m and $m + 1$ harmonics when the so-called TAE couplet emerges. The couplet of two harmonics can be a stand-alone eigenmode solution. The coupling occurs at a point where two continua intersect, i.e., $k_{\parallel m} = -k_{\parallel m+1}$ and thus the value of the safety factor at which TAEs develop is given by $q_{TAE} = \frac{m+1/2}{n}$. When TAEs are formed, the Alfvénic m^{th}

Fig. 3 (A) Experimental observations of Alfvénic eigenmode excitation in DIII-D by neutral beam-injected ions in a reversed shear plasma. Safety factor profile is indicated by «q» and electron temperature profile by «T_e». Measurements of a temperature fluctuation spectrum using the electron cyclotron emission (ECE) diagnostic is shown by the colored contours. Its numerical analysis using NOVA ideal MHD code indicates the presence of several reversed shear Alfvén eigenmodes (RSAE) and toroidicity-induced Alfvén eigenmodes (TAEs) corresponding to different toroidal mode numbers. (B) shows the radial variation of the predicted frequency of various classes of Alfvén eigenmodes: the TAEs, the ellipticity-induced Alfvén eigenmodes (EAE) and the beta-induced Alfvén eigenmodes (BAE) (Van Zeeland et al., 2006).

harmonic interacts with its neighbor, the $(m + 1)^{th}$ harmonic. The TAE location and its radial extent can be measured in experiments and compared with simulations in Fig. 3B.

The frequency of the couplet, $\omega_{TAE} = v_A/2q_{TAE}R$, is often considered as the nominal TAE frequency. If the magnetic shear is not too small the couplets are combined into a global TAE solution to be found numerically (Cheng and Chance, 1986).

Another, more complex expression for TAE frequency was derived analytically in the approximation of low inverse aspect ratio and low- β (Cheng, 1997):

$$\omega_{TAE}^2 = \left(\frac{v_A}{2qR}\right)^2 \left[1 + \frac{3}{2}\left(\frac{r_0}{R} + \Delta_{Sh}\right)^2 + 4\frac{\Delta_{Sh}}{R} + \frac{r_0^2}{R^2} - 2\frac{r_0\Delta_{Sh}}{R} + 2g^2\right], \quad (12)$$

where g^2 is the correction to the vacuum toroidal magnetic field from plasma equilibrium, r_0 is the minor radius of the mode location, and Δ_{Sh} is the Shafranov shift of the magnetic axis. The dispersion relation given by Eq. (12) provides the plasma parametric functional dependencies on the plasma equilibrium parameters, which are important in plasma diagnostics and in the stability studies of TAEs.

A single harmonic eigenmode, RSAE, was also measured, as shown in Fig. 3A (Van Zeeland et al., 2006). It is located at the maximum point of the Alfvénic m^{th} harmonic cocontinuum, i.e., at a point when its frequency is close to the continuum frequency. RSAEs, together with TAEs, are considered as the one of the most important eigenmodes limiting the energetic ion confinement. RSAEs are observed with their frequencies evolving on an equilibrium time scale, the frequency sweeping being characterized by a 30 – 100 ms timescale in present day devices, but with the timescale also depending on the toroidal mode numbers.

Characteristic AEs in 3D plasmas

The development of stellarators with sophisticated 3D geometries, allowing improved plasma confinement, has been a significant area of progress in recent magnetic confinement research (Mynick, 2006, see also Yamada, 2021).

The equations for AEs in stellarators have coefficients in 3D configurations which depend on both the toroidal and poloidal angles, leading to continuum gap formation through the mode coupling due to poloidal and toroidal variations of the equilibrium magnetic field. TAEs, in particular, have been found in stellarators experimentally and explained theoretically (Nakajima, 1996; Yakovenko et al., 2007).

The toroidal mode coupling is not important for TAEs/EAEs and GAEs/RSAEs in helical/stellarator devices such as LHD (Large Helical Device) with large toroidal period number, N , of the magnetic configuration (Fujiwara et al., 1999). A class of AEs for which toroidal mode coupling is essential exists only in 3D plasmas. In toroidal mode coupling, Fourier modes having the toroidal mode number, $n = n_1$, can couple with the Fourier modes having different, $n = n_2$, provided the condition $n_1 \pm n_2 = kN$ is satisfied, where $k = 0, 1, 2, \dots$. These modes consist of the mode family of $n = n_1$. The number of the mode families is finite, i.e., $1 + N/2$ (Schwab, 1993). Coupling among all modes belonging to the mode family of $n = n_1$ takes place and generates the helicity-induced Alfvén eigenmode (HAE) gaps (Nakajima et al., 1992; Kolesnichenko et al., 2001; Spong et al., 2003). The gap frequency can be evaluated analogously to the TAE frequency, by intersection of adjacent Alfvén continua as, $k_{\parallel m, n} = -k_{\parallel m+\nu, n+\nu N}$. Here, the magnetic field strength B is decomposed in a Fourier expansion with Boozer coordinates (Boozer, 2004) (ψ, θ, ϕ) as, $B = B_0 \left(1 + \sum_{\mu, \nu} \epsilon_B^{\mu, \nu}(\psi) \cos(\mu\theta - \nu N\phi) \right)$. The gap frequency is expressed as follows: $f^{\mu, \nu} = (\nu q^* N - \mu) \left(\frac{v_A}{4\pi R q} \right)$ and $q^* = \frac{2m+\mu}{2n+\nu N}$. This

expression corresponds to the gap frequency of the TAE with $\mu = 1, \nu = 0$, and the EAE with $\mu = 2, \nu = 0$. Typical stellarator configurations have helical coils of $l = 2$ polarity, i.e., where the coils correspond to the dominant helical component $\cos(2\theta - N\phi)$. The HAE is called HAE₂₁ here. As seen from the equation, the HAE frequency is approximately a factor of N larger than the TAE frequency. The HAE frequency is close to the TAE frequency in stellarators with medium and low N ($\approx 2 - 5$), and the HAEs may have noticeable impacts on EP transport, while the HAE frequency in high N stellarators, such as LHD ($N = 10$), is much higher than the TAE frequency. The coherent magnetic fluctuations in high beta LHD plasmas at lower toroidal field ($B_0 = 0.6$ T) were consistently interpreted as HAEs. The observed mode frequency lies above the lower bound of the HAE gap (Yamamoto et al., 2003).

In LHD plasmas with $N \gg 1$, TAEs, EAEs, GAEs and reversed shear Alfvén eigenmodes (RSAE) are essentially the same as in tokamak plasmas.

Kinetic TAEs

It was pointed out by Mett and Mahajan (1992) that a shear Alfvén wave may have significant coupling to kinetic Alfvén wave (KAW) in the vicinity of a TAE-gap where the radial structure of MHD-type shear Alfvén wave is peaked and the Larmor radius parameter, $k_{\perp}^2 \rho_i^2$, is not negligibly small. In particular, a TAE with frequency at the bottom of the gap couples to two outgoing KAWs with poloidal mode numbers m and $m + 1$, which propagate in radius and thus radiate away the energy of the TAE. This effect is called “radiative damping” of the TAE, which could be quite significant in hot plasmas, plasmas with high T_e/T_i , and for TAE mode structures with high radial gradients of plasma pressure.

At the top of the TAE-gap, KAWs with poloidal harmonics m and $m + 1$ propagate in radius toward each other. Two important effects result from this. Firstly, the outgoing energy flux resulting from the interference, is relatively small. Therefore, the radiative damping of a mode with frequency at the top of TAE-gap is much smaller than that of a mode at the bottom of TAE-gap. Secondly, waves with frequency above the TAE-gap, due to the finite Larmor radius of the first order in $k_{\perp}^2 \rho_i^2$, form a discrete spectrum of Kinetic Toroidal Alfvén Eigenmodes (KTAE), instead of the Alfvén continuum. In contrast to KAW eigenmodes considered in (Rosenbluth and Rutherford, 1975) and (Connor et al., 1983), the toroidicity effect that couples two poloidal harmonics is essential for KTAE existence (Candy and Rosenbluth, 1994; Breizman and Sharapov, 1995). To describe KTAE structure satisfactorily, the coupled system of MHD equations for TAE needs extra terms derived from the finite (i.e., non-zero) Larmor radius (FLR) of the particles.

The radial structure of the KTAE is similar to that of the TAE, apart from a narrow region at the TAE-crossing point of $q(r_{TAE}) = \frac{m+1}{n}$, where the mode width of KTAE is $\Delta r \sim \frac{\rho_i}{\epsilon^{1/2}}$. In comparison with TAEs, KTAEs have much lower radiative damping rate, but, due to their higher frequency, KTAEs experience somewhat lower drive by energetic particles. Also due to their anti-ballooning mode structure (with maximum amplitude at the high field side of the torus) KTAE can hardly be excited by trapped energetic ions produced with, e.g., ICRH, since the trapped ions are localized at the low field side of the torus.

KTAEs were searched for, and found experimentally on JET (Fasoli et al., 1996). Many KTAE modes arise above the TAE frequency, as was confirmed with TAE-antenna active diagnostics on the JET device, but their excitation by ICRH-accelerated trapped ions was rare. However, KTAEs can contribute to transport of passing α -particles and beam-injected ions similarly to TAEs.

Low frequency Alfvénic modes: BAEs, BAAEs

Below the characteristic TAE and RSAE frequencies, further gaps exist in the Alfvénic continuum and additional AE modes are found to be associated with these gaps which are products of the coupling of the Alfvénic and acoustic plasma oscillations. The Alfvén polarization branch is pushed up in frequency by finite beta effects by the value of the GAM frequency. (GAM or geodesic acoustic mode is another fundamental plasma oscillation required to be present in plasma simulations. They are important to correctly compute AE frequencies as well as the plasma turbulence.) A schematic of the low frequency gap structure and how it is formed by the finite plasma pressure effects from the Alfvénic continuum in a cylindrical approximation to toroidal geometry, are shown in the Fig. 4.

One can see that below the GAM frequency there is another, beta induced Alfvén-acoustic eigenmode (BAAE) gap, which is necessary to introduce in greater detail. The center of the BAAE gap can be estimated by comparing the sideband acoustic continuum, $\omega = v_A/q$, and the so-called “modified” Alfvén branch, $\omega = k_{\parallel} v_A / \sqrt{1 + 2q^2}$, which exists in the vicinity of the rational surface. Those uncoupled branches are shown in Fig. 4A.

Fig. 4 Low frequency Alfvén-acoustic continua depicted for the cylinder equilibrium (left) and for the torus (right). Curves A (blue color) refer to the Alfvén branches whereas curves a correspond to the acoustic branch. Vertical axis is the frequency squared and horizontal axis is the radial variable, chosen here as safety factor, q , so that m/n is the location of the rational surface.

Thus, the center of the BAAE gap is at the frequency

$$\omega_{BAAE} = \frac{\gamma\beta_p}{2q^2} \frac{v_A/R_0}{1 + \sqrt{\gamma\beta_p/2}\sqrt{1+2q^2}}, \quad (13)$$

and the width of the BAAE gap is $\Delta\omega = (\gamma\beta_p/q)\sqrt{1+2q^2}$.

Moreover, in [Gorelenkov et al. \(2007a\)](#) and [Gorelenkov et al. \(2007b\)](#) these gaps were numerically shown to contain eigenmodes, beta induced Alfvén-acoustic eigenmodes (BAAEs). The eigenmodes are localized near the accumulation points (extrema continuum points) of the gaps. Experimentally they are shown to agree with the ideal MHD code NOVA simulations ([Gorelenkov et al., 2007a](#)).

A particularly surprising experimental result relates to BAAE observations, since they are the product of the coupling to the acoustic branch. Thus, BAAEs are subject to strong thermal ion Landau damping. It is then expected that these modes should be excited in a region of parameter space where the electrons have significantly higher temperature than the ions, $T_i \ll T_e$. Nevertheless, BAAEs were excited and identified in many toroidal devices such as NSTX, JET ([Gorelenkov et al., 2007a,b](#)), DIII-D, HL-2A ([Yi et al., 2012](#)) and also reported from AUG ([Curran et al., 2012](#)) when electrons had a comparable temperature to the ions. The Alfvén acoustic gaps are much more complex ([Kolesnichenko et al., 2011](#)) in helical devices such as stellarators and these phenomena are at an initial stage of experimental studies ([Bertram et al., 2012](#)).

Because the BAAE frequency is associated with the safety factor profile, it can be used to infer the q value at the location of BAAE excitation. This important technique is discussed in section “**Implications for plasma diagnostics, MHD spectroscopy.**”

Alfvén-acoustic continuum and the sea of modes

The discovery of the low frequency Alfvén acoustic modes enriched the understanding of these low frequency, potentially deleterious, instabilities ([Gorelenkov et al., 2009](#)). In addition to the aforementioned TAEs, there are many other eigenmodes present in the plasma which can be associated with the Alfvénic waves, i.e., those which have phase velocity equal to the Alfvén speed. As an example of the continuum formed by two fundamental oscillations, the Alfvénic and the acoustic, the instability diagram computed for an ITER plasma is illustrated in [Fig. 5](#) ([Gorelenkov et al., 2008](#)). It includes several gaps where different eigenmodes were found theoretically and experimentally in current devices, including the beta induced Alfvén-acoustic eigenmode, beta induced Alfvén eigenmode, toroidicity induced Alfvén eigenmode, and ellipticity induced Alfvén eigenmode gaps. The figure also shows schematically the location of higher frequency compressional Alfvén eigenmodes (CAEs) and of the global Alfvén eigenmodes (GAEs).

Implications for plasma diagnostics, MHD spectroscopy

The phenomena which energetic particle induce, such as collective instabilities, reveal important information about the plasma. A knowledge of the properties of the resonant particles and the properties of the underlying modes is instrumental in the development of relatively straightforward techniques for measuring plasma parameters. Consider just the frequency of the modes as an example. The detection of Alfvénic instabilities driven by fast ions was proposed as a plasma diagnostic technique by [Fasoli et al. \(2002\)](#). Instability frequencies and mode structures are well understood via linear perturbative theories and can therefore serve as the basis for so-called MHD spectroscopy. This method allows information about the macroscopic plasma properties and the energetic particles to be extracted.

MHD spectroscopy was first proposed as an *active* measurement technique, involving the use of the stable shear Alfvén waves excited by antennas or internal coils ([Goedbloed et al., 1993](#)). It was then extended to include Alfvén eigenmodes excited by EPs in a plasma ([Sharapov et al., 2001](#); [Fasoli et al., 2002](#)). Further extension to Alfvén acoustic modes (BAAEs) was developed

Fig. 5 Prediction of ITER Alfvén-acoustic continuum, plotted as a function of normalized minor radius, r/a , obtained with the help of the ideal MHD code NOVA at $n = 12$. Several of the lowest frequency gaps are plotted, corresponding to BAE, TAE, EAE and BAAE modes. The continua are upshifted by the coupling of the Alfvénic and acoustic waves as explained above.

by Gorelenkov et al. (2009). If both *active* and *passive* spectroscopies are combined, EP driven modes can help to provide a powerful technique for the accurate determination of plasma equilibrium information in toroidal plasmas.

As discussed by Fasoli et al. (2002) collective modes must satisfy certain conditions to be suitable for application to MHD spectroscopy. Firstly, their dispersion relation should depend on macroscopic plasma properties which are distinct from the EP instability drive. The modes should also persist without suffering strong damping, i.e., the eigenmode phase velocity should not be close to the electron and ion thermal speeds. A third requirement is that the frequency range of the modes should be far from the frequency range of background micro-turbulence. Finally, the mode amplitude should not be so high that the modes significantly affect the EP confinement and bulk plasma properties. Alfvén eigenmode instabilities typically satisfy these requirements.

Fig. 6 Application of the MHD spectroscopy technique using observations of two distinct types of Alfvén eigenmode: left figure shows the technique applied to NSTX, where observations of RSAEs with different toroidal mode numbers, n , were used to derive the time evolution of the value of q_{min} , the minimum value of the safety factor in the plasma core. Also shown are two further experimentally measured values of the time evolution of q_{min} which are in good agreement with that derived from MHD spectroscopy: the equilibrium reconstruction values of q_{min} (solid squares) and MSE (motional Stark effect diagnostic) inferred values (solid line). The right figure represents a similar exercise using observations of BAAE modes in the same device, where q_{min} fit shows the time evolution of q_{min} derived from BAAE observations and q_{min} (MSE) that derived from the motional Stark effect diagnostic.

This spectroscopic method was applied to the NSTX experiment by Fredrickson et al. (2007), from which the illustration shown in Fig. 6 (left) is adopted. The physics underlying the interpretation of the results is that the GAM frequency is just below the shear Alfvén continuum frequency if corrected for the toroidal plasma rotation. To remove the frequency shift due to the pressure gradient, the safety factor should be close to 1. This helps to explain the good agreement of the time evolution of the q_{min} plots derived from the MHD spectroscopy with those determined by MSE measurements. The knowledge of q_{min} and its time evolution is often critical for designing and understanding plasma scenarios

A similar technique was applied to BAAEs with an up-swept frequency satisfying the modified Alfvénic branch dispersion, $\omega = k_{\parallel} v_A / \sqrt{1 + 2q^2}$ (Gorelenkov et al., 2009). Results of q_{min} reconstruction from such an application are shown in Fig. 6 (right). The advantage of the latest technique is that there is no frequency shift due to the GAM or the pressure gradient.

Nonlinear evolution of EP-driven modes and energetic particle transport

To understand how AEs behave on long timescales characteristic of EP slowing-down and plasma confinement and what could be the results of the AE interaction with energetic particles, i.e., for making projections for future burning experiments, the nonlinear phase of the AE instabilities must be investigated. For shear Alfvén waves excited by EPs, the main effect to be considered is the wave-particle nonlinearity affecting the slope of the EP distribution and the AE amplitude and its phase. On a long timescale, the coupled AE/EP dynamics is determined mostly by the competition between the electric field of the AE, which tends to flatten the EP distribution function, and collisional effects restoring the unstable EP distribution. The latter could be due to Coulomb collisions or other mechanisms such as interaction with ICRH waves.

The nonlinear phase of a single EP-driven mode observed experimentally may exhibit several scenarios, which could be categorized in terms of the mode amplitude and the mode frequency. Namely, the nonlinear temporal evolution of the mode amplitude could be either steady-state, bursting (a rapid increase of the amplitude followed by a decrease and a longer quiet period), or having either periodic or chaotic time modulation. In the case of a steady-state mode amplitude, the amplitude saturation is related to formation of a plateau in the EP distribution near the resonance. The case of a bursting AE amplitude is associated with generation of long-living nonlinear fluctuations, holes and clumps, in the EP distribution. The holes and clumps propagate in the phase space and have frequencies which sweep significantly from an initial value (by as much as 50% in some circumstances). The cases of periodic and chaotic amplitude modulation correspond to an EP distribution function oscillating around the plateau, but with amplitude insufficient for triggering a self-sustained nonlinear hole or clump. Theory of nonlinear mode evolution (Berk et al., 1996) rather well describes the qualitative nonlinear physics in so-called “near-threshold” approach of a single mode with very few key parameters involved (see section “Nonlinear models”).

In the case of multiple EP-driven modes, the experimental data is more complex in both linear and nonlinear phases. Often, out of several possibly unstable modes excited by the same EP population, only one type of mode becomes dominant, e.g., RSAEs dominate over TAEs in the Advanced Tokamak scenarios. Sometimes EP-driven modes are excited over a wide frequency range in an “avalanche” event such as observed on NSTX (Fredrickson et al., 2013; White et al., 2020). On a long timescale and with many EP-driven AEs, a plateau in EP distribution formed for one AE is not a plateau for other AEs, and so a “global” plateau is formed over much broader phase space when a steady-state AE scenario takes place. The bursting amplitude AE scenario can hardly be typical of the multiple AE case since the frequency sweeping range is much larger than the AE frequency separation.

Arguably the studies of the nonlinear effects are not as advanced as their linear counterparts. However, they are critical for building credible predictive models for EP relaxation in both velocity and real space.

Nonlinear models

The research in this area capturing the essence of the underlying physics in a theoretically tractable manner is highlighted below and includes significant progress achieved by several nonlinear models that describe rather well the observed evolution of energetic particle driven modes in experiments.

In burning plasmas conditions, such as in ITER, the characteristic time scales for building up the EP component has to be gradual and much longer than the Alfvénic growth time, $1/\gamma_L$, where γ_L is the linear growth rate. Under such conditions the nonlinear processes associated with relaxation of the EP distribution due to AEs require near-threshold consideration. A series of works on this topic emerged from the nonlinear kinetic treatment of Alfvénic instabilities using the 1D bump-on-tail problem, which became known as the Berk-Breizman (often abbreviated to BB) model (Berk et al., 1996). It includes the collision term (representing particle annihilation and injection processes) and wave damping.

An important parameter of the BB model is the ratio of the effective collision frequency to the linear growth rate $\hat{\nu} \equiv \nu_{eff}/\gamma$, where the growth rate γ is determined by the difference between the linear growth rate and the background dissipation γ_d : $\gamma = \gamma_L - \gamma_d$. $\hat{\nu}$ restores the distribution function of the resonant particles in the velocity space near the resonances. A cubic nonlinear non-local equation was derived (Berk et al., 1996) that depends upon the single control parameter $\hat{\nu}$:

$$\frac{dA}{d\tau} = A(\tau) - \frac{1}{2} \int_0^{\tau/2} dz z^2 A(\tau - z) \int_0^{\tau-2z} dx e^{-\hat{\nu}(2z+x)} A(\tau - z - x) A(\tau - 2z - x), \quad (14)$$

where A is the amplitude of the mode and $\tau = (\gamma_L - \gamma_d)t$ is the normalized time. The scattering frequency, $\hat{\nu}$, accounts for the competition between the mode itself and the relaxation processes which recovers the initial distribution. A more sophisticated cubic equation was subsequently derived which includes the velocity slowing down and has different integrand than Eq. (14) (Lilley et al., 2009).

Solutions of this equation at different values of $\hat{\nu}$ are summarized in Fig. 7 (Berk et al., 1996). At low collisionalities, $\hat{\nu} < 4.4$, the solution pulsates, with more complex time oscillations becoming irregular at lower scattering. The solutions show a well-defined sequence of transitions as $\hat{\nu}$ is decreased from periodic, through multiply periodic, to chaotic behavior. At very low collisionality an explosive behavior emerges, i.e., when the assumption in the derivations breaks down and when the amplitude becomes large enough. It is possible to consider the saturated steady-state solution of that system as a fixed point of the system dynamics.

The cubic equation of nonlinear mode behavior, Eq. (14), breaks down if the particle response needs to be considered. Such a consideration was published as a conjecture that structures are formed in the fast ion distribution function (holes and clumps) corresponding to a deficit or the surplus of fast ions (Berk et al., 1997). In later simulations these structures were confirmed with the help of a fully nonlinear Vlasov-Maxwell code (Lilley et al., 2010). Holes and clumps support long-lived nonlinear BGK waves

Fig. 7 Solutions of the cubic equation Eq. (14) for the nonlinear amplitude evolution of a model fast ion driven, but marginally unstable modes at $A(0) = 1$ and various values of $\hat{\nu}$: (A) $\hat{\nu} = 5.0$, (B) $\hat{\nu} = 4.3$, (C) $\hat{\nu} = 3.0$, (D) $\hat{\nu} = 2.5$, and (E) $\hat{\nu} = 2.4$. Note that $\hat{\nu} \equiv \nu_{eff}/\gamma$, where ν_{eff} is the effective collision frequency of the energetic particles and γ is the linear growth rate of the mode. The significance of the different plots is discussed in the text.

Fig. 8 Frequency chirping of an unstable mode during a shear optimized JET tokamak plasma discharge using deuterium-tritium fuel. The characteristic frequency change is $\sim 5\%$ over ~ 1 ms. The spectrum is measured by the magnetic field probes a.k.a. Mirnov coils.

(Bernstein et al., 1957) where the background dissipation is balanced by the chirping (i.e., frequency sweeping) behavior. The predicted frequency chirping was seen in JET DT operation, as show in Fig. 8 (Pinches et al., 2004).
